Sleep hygiene should be emphasized in the treatment of any chronic insomnia, including psychophysiological insomnia. Principles of good sleep hygiene are summarized in Table 60–6.

TABLE 60–6. Sleep hygiene

Regular sleep time	Establishing a regular sleep–wake schedule is very important, especially a regular time to awaken in the morning, with no more than 1-hour deviation from day to day, including weekends. Arousal time is perhaps the most important synchronizer of circadian rhythms. Awakening at 6:00 A.M. on weekdays to go to work and then sleeping until noon on weekends should be discouraged.
Proper sleep environment	Sleep interruptions should be minimized. The bedroom should be cool, dark, and quiet. The clinician needs to inquire specifically about noise, because patients may habituate to a noisy sleep environment and may not remember the noise, even though it continues to disrupt their sleep pattern. Patients who have convinced themselves that they can sleep only with the radio or television on should be discouraged from this practice. Attention to the radio or television may prevent their minds from wandering, or may keep them from beginning to worry about other matters, and thus assist with sleep latency, but the continuing noise will be a disruptive factor during the course of the night. Clock radios that automatically turn off may be useful.
Wind-down time	Time to wind down before sleep is important. The clinician should advise patients to stop work at least 30 minutes before sleep-onset time and to change their activities to something different and non-stressful, such as reading or listening to music.
Stimulus control	This procedure, an important component of sleep hygiene, involves removing from the bedroom all stimuli that are not associated with sleep. The bedroom should be used for sleep and, of course, sexual activity (which is often conducive to sleep). Activities such as eating, drinking, arguing, discussing the day's problems, and paying bills should be done elsewhere, because their associated arousal may interfere with sleep onset.
Avoidance of poorly timed alcohol and caffeine	Caffeine is quite disruptive of nocturnal sleep in many patients, and it has a long half-life. Thus, caffeine consumption should be limited to the forenoon and in some individuals not be continued after noon. A glass of wine or beer in the evening may help some individuals relax, but regularly having several drinks before bedtime for the express purpose of using the alcohol as a sedative should be discouraged. Alcohol in large doses can substantially disrupt and fragment sleep. Cigarette smoking may produce or aggravate insomnia in some patients.

Late-night high-tryptophan snack	A bedtime snack such as a glass of milk, a cookie, a banana, or a similar high-tryptophan food may help promote sleep onset in some patients.
Regular exercise	Periods of exercise for 20–30 minutes at least 3–4 days a week should be encouraged. Improved aerobic fitness has been shown experimentally to promote slow-wave sleep. Exercise should not occur within 3 hours of bedtime, however, because the autonomic arousal accompanying the exercise may serve to delay sleep onset.

Biofeedback

Biofeedback treatment that directly teaches patients how to control autonomic functioning may be a useful therapeutic strategy (Hauri et al. 1982). Biofeedback may serve the dual function of enhancing a sense of self-control and reducing autonomic arousal. Although electromyography (EMG) and skin temperature biofeedback systems are perhaps the most commonly available forms, EEG biofeedback has been shown to be useful in some cases of chronic insomnia (Cortoos et al. 2006).

Sleep Restriction

Some patients with chronic insomnia (especially elderly patients) spend greater and greater amounts of time in bed achieving less and less sleep, such that they may be in bed 10 hours or more and sleep only 6 hours. Sleep tends to spread out among the hours spent in bed, and this process further fragments nocturnal sleep. The principle of sleep restriction is to decrease substantially the time spent in bed so that sleep will consolidate to that time (Spielman et al. 1987). Restricting time available for sleep results in enhanced consolidation (which has important benefits in terms of improving actual and perceived sleep quality) and an improved subjective sense of self-control over sleep habits. The steps involved include the following:

1. Have the patient maintain a sleep diary for at least 5 nights. This diary should include a) time to bed at night, b) estimated time of sleep onset, c) number and estimated time of awakenings during the night, d) time of final awakening in the morning, and e) time out of bed. From this 5-night sleep diary data, calculate the mean value for estimated total sleep time (TST) and percentage sleep efficiency: TST divided by total time in bed.
2. Set the beginning total time in bed to equal the mean TST. For example, if the patient's estimate of his or her TST per night averaged over 5 nights is 5½ hours, set the time in bed to no more than 5½ hours, perhaps having the patient go to bed at 12:30 A.M. and get up again at 6:00 A.M. This restriction will result in increased daytime sleepiness the first several days, so the patient may need encouragement to continue with the program.
3. Instruct the patient to call in, usually to an answering machine, every morning while in the program and report his or her sleep data for the previous night, including time to bed, time of awakenings during sleep, time of final awakening, and time out of bed.
4. Calculate TST and sleep efficiency for each night. When mean sleep efficiency for 5 consecutive nights reaches 85% or better, increase time in bed by 15 minutes, by allowing the patient to go to bed 15 minutes earlier. If mean sleep efficiency declines to less than 85%, decrease time in bed by 15 minutes (but not within the first 10 days of treatment). Naps outside the prescribed time in bed are not allowed.
5. Repeat the above procedure until the patient is maintaining a sleep efficiency of 85% or better and obtaining what he or she considers to be a subjectively adequate amount of nocturnal sleep.

Sleep restriction results in some unavoidable sleepiness at the beginning of the regimen, and not all patients can complete this treatment. However, those who can have a substantial chance of improving their sleep efficiency and achieving greater satisfaction with their sleep.

Pharmacological Treatment Options for Chronic Insomnia

The use of hypnotic agents in the treatment of insomnia has a long and checkered history. Early sedative-hypnotic agents such as the barbiturates, and then agents such as Noludar, Placidyl, Quaalude, and Doriden, with their potential lethality, disruption of sleep morphology, and addiction and/or habit-forming tendencies, gave the word "hypnotic" a bad reputation, to a considerable extent well deserved at the time. Such agents no longer have a place in the routine treatment of insomnia. Although chloral hydrate (500–1,000 mg) is still available for hypnotic use, it is associated with increased addiction potential and has a relatively limited range between effective and lethal dose; thus, it might best be reserved for occasional use when indicated for other reasons.

Mendelson and Jain (1995) suggested that the ideal hypnotic would have a therapeutic profile characterized by rapid sleep induction and no residual effects (including memory effects). Its pharmacokinetic profile would include rapid absorption and optimal half-life, as well as specific receptor binding and lack of active metabolites. Its pharmacodynamic profile would include lack of tolerance or physical dependence and no CNS or respiratory depression. Although the ideal hypnotic agent has yet to be developed, hypnotic agents are being systematically improved with respect to most of the foregoing issues.

When the benzodiazepines came on the scene in the latter part of the twentieth century, with their prominent and useful sedative, hypnotic, anxiolytic, and anticonvulsant effects, safety was improved, but habituation, tolerance, and altered sleep morphology (decreased SWS) were side effects of concern. Because these agents activate the multiple benzodiazepine receptors in the brain and enhance CNS GABAergic inhibition, they have a role in insomnia related to anxiety, where their anxiolytic and GABAergic hypnotic effects are useful. Benzodiazepine agents approved by the U.S. Food and Drug Administration (FDA) for the treatment of insomnia are listed in Table 60–7.

TABLE 60–7. Benzodiazepine agents for treatment of insomnia

Drug	Half-life (hours)	Absorption	Typical dose (mg)	Active metabolite
Triazolam (Halcion)	2–5	Fast	2.5–10	No
Temazepam (Restoril)	8–12	Moderate	7.5–30	No
Estazolam (ProSom)	12–20	Moderate	1–2	Minimal
Quazepam (Doral)	50–200	Fast	7.5–15	Yes
Flurazepam (Dalmane)	50–200	Fast	15–30	Yes

The benzodiazepine compounds differ substantially in terms of half-life, and the clinician can choose the agent with a half-life most appropriate for the clinical situation. A long-half-life hypnotic such as flurazepam (15–30 mg) or quazepam (7.5–15.0 mg) might be appropriate for an anxious patient in whom daytime anxiolytic effects are helpful if the interference with psychomotor performance is acceptable and tolerable and if both patient and physician realize that considerable buildup in blood level can be expected. Patients with difficulty sleeping through the night might benefit from intermediate-half-life agents such as temazepam (15–30 mg) or estazolam (1–2 mg). Patients who must be alert in the morning without residual daytime sedation would best be managed with a short-half-life agent such as triazolam (0.125–0.25 mg). Many other benzodiazepines have been used for insomnia because of their sedative-hypnotic properties, but current thinking suggests that these agents might best be reserved for those patients who have significant anxiety or who have perhaps not responded to newer hypnotic agents.

Several new nonbenzodiazepine hypnotic agents have been developed that appear to act on the omega$_1$ benzodiazepine receptor but carry less potential for the problems that may accompany benzodiazepine use, such as habituation, tolerance, and altered sleep patterns. These newer nonbenzodiazepine agents generally have in common demonstrated efficacy in treating insomnia, differing primarily in half-life and effective duration of action (Table 60–8).

TABLE 60–8. Nonbenzodiazepine agents for treatment of insomnia

Drug	Half-life (hours)	Absorption	Typical dose (mg)	Active metabolite
Zaleplon (Sonata)	1–1.5	Fast	5–20	No
Ramelteon (Rozerem)	1–2.6	Fast	4–8	Yes
Zolpidem (Ambien)	1.5–2.6	Fast	2.5–10	No
Zolpidem ER (Ambien CR)	2.8	Fast	6.12–12.5	No
Eszopiclone (Lunesta)	6	Fast	7.5–15	Yes

Zolpidem is an imidazopyridine agent active at the omega$_1$ benzodiazepine receptor but without the same degree of potential for tolerance or rebound seen with the benzodiazepines. Zolpidem has shown no evidence of rebound insomnia after being used at 10 mg/day for up to 35 days (Monti et al. 1994; Scharf et al. 1994; Ware et al. 2007). An extended-release (XR) form of zolpidem is available that extends duration of action about 1.5 hours. Its use over a 6-month period is associated with minimal residual and rebound effects (Owen 2006a).

Zaleplon is a nonbenzodiazepine pyrazolopyrimidine sedative-hypnotic agent that also acts as a benzodiazepine receptor agonist. With a short half-life of about 1.5 hours, this agent can be administered during middle-of-the-night awakenings as long as the patient has 4 hours of possible sleep time remaining (Zammit et al. 2006). Its short duration of action provides a somewhat more favorable safety profile for adult and elderly patients (Israel and Kramer 2002).

Eszopiclone is a nonbenzodiazepine cyclopyrrolone agent with rapid absorption and a half-life of about 6 hours. Eszopiclone is extensively metabolized by oxidation and demethylation, and the cytochrome P450 (CYP) isozymes CYP3A4 are involved, thus agents that induce or inhibit these enzymes may influence the metabolism of eszopiclone. Some individual report a bitter taste as a side effect (Najib 2006).

As a group, these agents appear to be relatively safe and effective for insomnia complaints, differing primarily in regard to half-life. With this increased safety and resulting increased worldwide use has come potentially significant problems associated with their inappropriate use or misuse, most often involving either 1) routine prescription without adequate preliminary differential diagnosis (the clinician's problem), and/or 2) taking the medication at an inappropriate time such as before having retired to bed (most often the patient's problem), resulting in inappropriate and potentially dangerous drug-induced waking behaviors. This is an issue related to proper differential diagnosis and proper treatment planning and monitoring, which needs to be addressed by improved education (still unfortunately often relatively sparse in medical school curricula). The 2005 NIH Consensus Conference on Chronic Insomnia in Adults recommended that these newer nonbenzodiazepine hypnotic agents be considered as the first-line treatment for insomnia rather than the traditional benzodiazepines. While not significantly altering sleep morphology, these agents do not specifically increase SWS, an attribute thought to be possibly desirable based on the role of SWS in memory function.

Additional recently developed agents include the melatonin MT_1 and MT_2 receptor agonist ramelteon, approved for use in insomnia with no long-term-use restrictions (Owen 2006b). Ramelteon is thought to promote sleep by influencing homeostatic sleep signaling mediated by the suprachiasmatic nucleus (Pandi-Perumal et al. 2007). It was shown to be effective for treatment of primary insomnia in elderly adults at a dose of 4 mg or 8 mg, with no evidence of adverse next-day effects (Roth et al. 2007b).

Several agents that are not yet formally approved for the treatment of insomnia have been found to selectively increase SWS. Sodium oxybate, a sedative-hypnotic agent that has been shown to increase SWS, is currently FDA approved only for use in treating narcolepsy. Its potential for abuse and limited

availability are issues of concern. Tiagabine, a GABA reuptake inhibitor that increases synaptic GABA through selective inhibition of the GABA transporter type 1 (GAT-1), has been shown to increase SWS in a dose-dependent fashion in primary insomnia at doses up to 8 mg (Walsh et al. 2006). Gaboxadol, a selective extrasynaptic $GABA_A$ agonist, has been demonstrated to increase SWS at a dose of 15 mg (Deacon et al. 2007) and to improve sleep in a phase-advance model of insomnia (Walsh et al. 2007a). Lankford et al. (2008) reported results of two randomized, placebo-controlled studies of the use of gaboxidal over a 30-night period in both young adult and elderly patient with primary insomnia. Subjects treated with gaboxidal demonstrated enhancement of PSG-measured sleep maintenance and SWS as well as improvement in subjective sleep measures. The unique extrasynaptic mechanism of action of gaboxadol involves a $GABA_A$ receptor well represented in the thalamus, suggesting a quite different mechanism of action than most other GABA agents (Wafford and Ebert 2006).

The FDA has recommended limitations on quantities and duration of use for many hypnotic agents, although several recently approved agents (e.g., eszopiclone, zolpidem ER, ramelteon) have no such limitations.

There are a number of other sedative agents, many of them among the tricyclic antidepressant arsenal, that have been used for insomnia, including amitriptyline, nortriptyline, trimipramine, and doxepin (which are generally antihistaminic). Trazodone is also frequently prescribed. While clearly indicated when insomnia complicates depression, their general use for insomnia has neither FDA approval nor solid scientific backing. Special caution should be used in patients with increased risk factors such as cardiac conduction defects, glaucoma, or seizure disorders. Similar considerations exist for sedating atypical antipsychotic agents, which while often quite useful for insomnia complaints, should remain in the domain of patients experiencing cognitive symptoms suggestive of possible thought disorder. That being said, the author has had patients with chronic insomnia nonresponsive to usual hypnotic agents that does respond well to very low bedtime doses of sedative tricyclics such as nortriptyline. It should be noted that a recent placebo-controlled study has found doxepin doses of 1, 3, and 6 mg to be effective for treatment of primary insomnia, demonstrating improvement of both PSG-determined and patient-reported sleep measures. Presumably at this dose the drug is acting primarily as an H_1 selective antagonist (Roth et al. 2007a). FDA approval for doxepin in this dose range for insomnia is pending.

Over-the-counter sleep agents and various herbal remedies found in health food stores have generally not been evaluated for hypnotic efficacy in well-controlled double-blind studies. Although some have modest sedative effects, consumers should be cautious, especially as concerns regular or excessive use of such agents.

The future may see the use of orexin-modulating agents in insomnia. Orexins are involved in sleep–wake stabilization and are deficient in narcolepsy, which is accompanied by excessive sleepiness. An orexin antagonist has been shown to induce sleep in both animals and humans, but is not yet available for clinical use (Brisbare-Roch et al. 2007).

Long-Term Use of Hypnotic Agents for Chronic Insomnia

The long-term use of hypnotic agents employed in the treatment of chronic insomnia is a topic of considerable concern. Short-term intermittent use is often recommended and remains a good overall principle. If a specific etiology, such as a medical or psychiatric disorder, can be identified and treated, the insomnia may resolve. Many, although not all, circadian rhythm disorders can be effectively managed with bright-light or melatonin treatment. Many patients with primary insomnia, however, may require long-term pharmacological management. In a recent study, long-term (6-month) treatment of chronic primary insomnia with eszopiclone 3 mg led to enhanced quality of life, reduced work limitations, and improved patient satisfaction with sleep without evidence of rebound insomnia following medication discontinuation (Walsh et al. 2007b). Several similar placebo-

controlled studies reported that 12.5 mg zolpidem ER administered 3–7 nights per week over a 6-month period resulted in improved daytime concentration and work performance as well as improved satisfaction with nocturnal sleep (Erman et al. 2008; Krystal et al. 2008).

The use of the lowest dose of the most innocuous but most effective agent is a good rule. Unnecessary withholding of treatment should be avoided, however. Considering the known adverse effects of chronic sleep loss, in the context of the current availability of relatively safe and effective hypnotic agents, there would appear to be no reason to withhold or to limit treatment in those patients for whom a comprehensive and thorough diagnostic evaluation has established the presence of a primary insomnia disorder that would benefit from long-term treatment. The cost–benefit ratio of chronic pharmacological treatment must be carefully evaluated on an individual patient basis.

Given the demonstrated effectiveness of CBT, it seems any patients being considered for long-term hypnotic treatment should at least be given the option of trying CBT to see if it might decrease the need for hypnotic use. The following three general rules might be useful to keep in mind when considering the long-term use of hypnotics:

1. Use the lowest effective dose and the shortest clinically indicated duration of use.
2. Do not put a patient on long-term hypnotic use for a chronic insomnia condition without including at the very least a good trial of behavioral treatment for insomnia.
3. Do not hesitate to prescribe long-term use of one of the newer and safer hypnotic agents when clinically indicated for an appropriately evaluated chronic insomnia condition (including but not limited to primary insomnia).

INSOMNIA IN THE ELDERLY

Up to 50% of older Americans report chronic difficulties with their sleep (Foley et al. 1995), and similar numbers have been reported from other cultures. In addition to resulting dissatisfaction with sleep and aspects of daytime performance, those with sleep complaints use health services to a greater extent (Novak et al. 2004). While the differential diagnosis and treatment strategies are similar in elderly individuals, there are both physiological and behavioral aspects of aging that impact sleep that require emphasis.

Normal Aging and Sleep Control Mechanisms

CNS changes associated with aging may adversely impact both Process S and Process C sleep control systems. There is evidence that the number of non-REM-promoting VLPO neurons in the hypothalamus decreases with age, beginning about after age 50 years, with the decrease being more pronounced in women than men (Hofman and Swaab 1989). By age 85 years, there may be a loss of 50% of VLPO neurons. To the extent that these VLPO neurons support the integrity of non-REM sleep, or Process S, this cell loss could be related to the increase in insomnia complaints in the elderly, especially women (Ancoli-Israel and Ayalon 2006). Additionally, the nocturnal production of melatonin decreases with age, significantly so by age 60 years, which may lead to impairment in the Process C circadian arousal control system (Cardinali et al. 2006). The possible impact of such changes should be taken into account in evaluating sleep complaints in the elderly—the use of hypnotics and/or melatonin supplementation may be especially useful (Haimov et al. 1995).

Those medical and psychiatric conditions adversely impacting sleep and sometimes comorbid with insomnia increase in frequency in the elderly, and specific sleep disorders, such as RLS, sleep apnea, and REM sleep behavior disorder, also increase in incidence with age. The comorbidity of insomnia and sleep-related breathing disorders in the elderly is associated with significant impairment (Gooneratne et al. 2006). Elderly people frequently take a variety of medications that, for a variety of reasons, may either interact or act differently in the elderly person and result in altered sleep patterns or sleep behavior.

Adverse Sleep Habits and Environments in the Elderly

Even the healthy elderly may live a lifestyle of restricted interests and decreased mental and physical activities, which can contribute to poorer sleep. Process S appears to be stimulated by the amount and intensity of the preceding day's mental and physical activity, and reductions in such can be expected to adversely impact Process S. Maintenance of a sleep-healthy lifestyle with vigorous mental and physical as well as social activities can certainly help here. The impact of exercise on sleep is still somewhat unclear (Driver and Taylor 2000; Kubitz et al. 1996); however, the role of improved aerobic fitness in health and well-being generally is well established.

The less healthy elderly, who may reside in more restrictive environments or nursing homes, are at special risk, not only because of the foregoing but because of the adverse impact of factors such as irregular schedules, excessive nocturnal lighting, noise, and other issues adversely affecting sleep. Efforts should be made to modify and improve the living and sleeping environment before routinely moving to pharmacological interventions such as sedative-hypnotic agents.

Treatment of Insomnia in Elderly Patients

Strict attention to good sleep hygiene is important, including not spending excessive time in bed and improving aerobic fitness if possible. Excessive use of caffeine, including that contained in over-the-counter analgesics, should be curtailed.

Bright-light treatment has been useful in treating sleep disorders, including morning bright light for certain cases of sleep-onset insomnia (possibly caused by a mild circadian phase delay), in elderly patients. Evening bright light has been found to be effective in sleep-maintenance insomnia in healthy elderly subjects (Campbell et al. 1995). It should be kept in mind that elderly individuals may be less responsive to bright light and therefore might require a greater duration or intensity of treatment (Duffy et al. 2007).

Use of pharmacological agents must be tempered by the awareness that half-lives may be extended, that risk of multiple drug interactions may be increased, and that lower-than-usual doses may be adequate. Zaleplon, because of its short half-life, may be a relatively safe agent in the elderly, and indiplon (15 mg), a nonbenzodiazepine hypnotic active at the benzodiazepine alpha$_1$ subunit, was shown to improve sleep in elderly patients with primary insomnia during a 2-week treatment period with no significant side effects (Lydiard et al. 2006). Indiplon could potentially be released as a hypnotic in the near future.

Some have suggested that use of hypnotics in elderly patients should be very conservative, with an emphasis on nonpharmacological strategies (Bain 2006; Sivertsen and Nordhus 2007) and CBT, which has been shown to be effective in elderly patients with insomnia. While concerns have been expressed about a relationship between hypnotic use and falls in the elderly, a recent study found that insomnia, but not hypnotic use, was associated with a greater risk of subsequent falls (Avidan et al. 2005).

Considering the cognitive difficulties experienced by many elderly individuals possibly related to sleep impairment, a recent study demonstrating improved cognitive function in an animal model of genetically induced impaired sleep following treatment with a benzodiazepine to help improve sleep might be important (Pallier et al. 2007). It has yet to be determined whether nonpharmacological treatment of insomnia is as effective as pharmacological in reversing the adverse cognitive effects of insomnia.

CONCLUSION

It is gratifying that the available treatment strategies for insomnia have improved coincidentally with our recognition of the importance of protecting sleep and treating insomnia in recent years. We are still left with an unclear understanding of the basic pathophysiology of many insomnia-related

syndromes, however, and until our knowledge base improves, we must depend on systematic differential diagnosis and treatment planning using the information available. Fortunately, with this approach, most patients with insomnia complaints can be significantly helped.

WHAT DOES MEDICATION CHANGE IN TREATING PERSONALITY?

Personality disorders are some of the more challenging psychiatric conditions and have traditionally been viewed by many clinicians as more difficult to treat than numerous Axis I conditions, often requiring investment in more lengthy treatments that involve a variety of modalities and approaches. It is also common to attain lesser and more modest degrees of success in treating personality disorders, with a recognition, however, that even partial modifications in people's dysfunctional interpersonal relationships, coping mechanisms, and symptomatology can bring about notably better adaptations. Psychotherapy continues to be the treatment foundation for all personality disorders, and psychotherapy studies of personality disorders on the whole find that patients with these disorders improve with treatment, with large treatment effects—two to four times greater than the improvement found in the control conditions (Perry and Bond 2000). In more recent years, the traditional psychodynamic therapy approaches have become enriched with more eclectic possibilities and structured therapies, such as dialectical-behavioral therapy for borderline personality disorder (BPD) (Linehan 1993) and various other cognitive psychotherapies (Tyrer and Davidson 2000). Although medications continue to be an adjunct to the treatment of personality disorders, and research medication treatment trials in personality disorders continue to be much fewer than those available in Axis I disorders, medications undoubtedly can play a useful role in the treatment of personality disorders, at least in some disorders and for some patients.

The main indications for using medications in treating personality disorders are periods of decompensation, crises, and hospitalizations; the longer-term management of symptom clusters that are maladaptive and may be responsive to medication; and the reappearance or worsening of comorbid Axis I conditions. Frameworks have been previously described conceptualizing the medication treatment of personality disorders (Coccaro 1993; Gabbard 2000; Kapfhammer and Hippius 1998). Such frameworks must address several interesting questions. Can medication treat the underlying personality disorder per se or simply some of its symptomatic manifestations? Is medication effective at targeting Axis II symptom clusters that lie on a dimensional continuum and are subclinical variants of Axis I conditions? Can medication, in addition, treat unique symptomatology that may be more temperament related and less Axis I bound? Reflecting on these questions necessitates a brief overview of the foundations of personality, as well as an overview of the kinds of changes over time that medication treatment studies of personality disorders examine and the methodological issues involved.

Overview of Personality

Personality can be broadly conceptualized as an admixture of *temperament,* which is strongly determined by genetics, and *character,* which is mainly environmentally shaped. Evidence from population twin studies indicates that personality disorders have a heritable component that presumably is attributable largely to temperament (Coolidge et al. 2001; Torgersen et al. 2000), with heritability estimates ranging from approximately 0.30 to 0.80, depending on the personality disorder. Additionally, symptom clusters within a personality disorder may have distinct heritabilities. For example, there is evidence in BPD that affective and impulsive traits show independent familial

transmission (Silverman et al. 1991).

One of the more widely used temperament models in the mainstream psychiatric literature is Cloninger's psychobiological model of personality, which delineates four basic and independent temperaments—novelty seeking, harm avoidance, reward dependence, and persistence—which contribute about 50% to the formation of personality (Cloninger et al. 1993). It was initially postulated that there was a single neurochemical axis underlying each temperament: dopamine for novelty seeking, serotonin for harm avoidance, and norepinephrine for reward dependence. However, recent genetic studies have not lent support to this simplistic conceptualization but have rather begun to suggest that each temperament dimension may be more complexly determined by several neurochemical systems and specific receptor types (Comings et al. 2000). In addition, we do not yet have behavioral genetic studies confirming the genetic nature of temperament and the nongenetic nature of character, and thus this traditional dichotomy must not be taken for granted (Cravchik and Goldman 2000).

Conversely, when character is being reflected on, other aspects of the personality are evoked, those presumed to be shaped by early parental influences, other environmental effects, trauma, and life stressors, leading to intrapsychic structure or organization characterized by particular self-representations, mechanisms for regulating self-cohesion and self-esteem, internalized object relations, defensive styles, and predominant cognitive schemata. The widely held assumption is that these constituents of character are not predominantly biologically driven and, therefore, are not highly amenable to medication treatment. Although the clinical wisdom of this outlook is largely taken for granted, some caution is called for. The degree to which aspects of character are biologically determined is a largely unexplored area, notable for the absence of studies rather than the presence of negative studies. This is due, at least in part, to the complexity of character concepts, which makes them more difficult to operationalize and study than simple symptoms, as well as the traditional divergence and absence of collaboration between psychodynamic and phenomenologically or biologically oriented scientists. On a second note of caution, the assumption that if something is strongly biologically driven, it will respond better to pharmacotherapy, and if it is more environmentally determined, it will be more amenable to psychotherapy, is partially a fallacy. Genetically, high cholesterol can be partly treated with appropriate diet. In strongly biologically driven disorders such as obsessive-compulsive disorder (OCD), pharmacotherapy and cognitive-behavioral therapy can have comparable therapeutic efficacy and are accompanied by similar brain activity changes (for details, see Baxter et al. 1992; Schwartz et al. 1996).

Medication and Personality Disorders

Unfortunately, aspects of character organization, and measures of these, traditionally have been excluded from pharmacological trials in treating personality disorders; thus, again we are faced with an absence of studies rather than negative studies. In one small study that partially addressed this question (Mullen et al. 1999), defense mechanisms as measured by the Defense Style Questionnaire and personality organization as measured by the Inventory of Personality Organization were assessed before and after treatment of major depression. Compared with the nonresponders, the responders showed a significant reduction in the use of primitive defenses. Personality organization did not change, but this was assessed in only a small subgroup of patients.

It does make sense that treating symptoms such as affective and impulse dysregulation could have a notable effect on self-perception, self-esteem, and relationships with others and thus could positively affect character, even if not modifying its core. Indeed, several treatment studies of Axis I disorders found a decrease in comorbid Axis II disorders after treatment of the target disorder, and this finding may in part reflect some shift in character structure when gross symptomatology is stabilized (Baer et al. 1992; Noyes et al. 1991). Furthermore, some evidence indicates that patterns of relationships between the more "biologically driven" temperament traits and the more "experience driven"

character traits may exist within a given personality disorder. For example, in BPD, the trait of affective instability has been found to be associated with the defenses of splitting, projection, acting out, passive aggression, undoing, and autistic fantasy, whereas the trait of impulsive aggression was positively associated with the defense of acting out and negatively associated with the defenses of suppression and reaction formation (Koenigsberg et al. 2001).

Another caveat in the biological versus nonbiological conceptualization of personality disorders is that some are typically viewed, with some supporting evidence, as more biologically driven than others, possibly lying on a continuum with biologically well-characterized Axis I disorders (Siever et al. 1991). The main biologically driven personality disorders are schizotypal personality disorder, which can be conceptualized as a schizophrenia spectrum disorder with supporting familial and biological data; BPD, which can be viewed as a mood spectrum disorder; and avoidant personality disorder, which may lie on a continuum with social phobia.

Gitlin (1993) described three conceptual frameworks for the pharmacotherapy of personality. The first is categorical, proposing that the medications treat the disorder itself as a whole. This model may be more plausible when one is considering the aforementioned more strongly biologically driven personality disorders. Although it is compelling to speculate that medications may treat more than the manifest symptoms of personality, as we just described, evidence for this is lacking, and we hope that it will be addressed by future study designs.

The second framework is dimensional, most supported by the literature to date, and the one adopted in this chapter. It proposes that pharmacotherapy targets core trait vulnerabilities, manifested as symptom clusters, that may cut across the various personality disorders or may even represent Axis I subclinical variants. The major four such dimensions that are consistently cited in the literature are cognitive–perceptual, impulsivity–aggression, mood instability–lability, and anxiety–behavioral inhibition (see Siever and Davis 1991; Soloff 1990). The various personality disorders thus present with various admixtures of these trait symptom clusters (these are described further in the sections detailing the pharmacological treatment of each disorder).

The third conceptual model speculates that in treating Axis II personality disorders with medication, efficacy results from the treatment of Axis I disorders that may be masked or distorted by the prominent personality features. For example, individuals with avoidant personality disorder may in fact have a very chronic and pervasive generalized type of social phobia that is being interpreted as personality pathology. This model, in our view, has become less useful in recent times as both clinicians and researchers have become more educated and adept in diagnosing on both axes and reflecting on their interactions.

Another important area in critically assessing the medication treatment trials of personality disorders is an awareness of the significant methodological challenges that face this field (Coccaro 1993; Gitlin 1993). A historical issue relates to the fact that the classification of personality disorders changed dramatically with the advent of DSM-III-R in 1987 (American Psychiatric Association 1987); therefore, treatment trials prior to that time can be extrapolated to only currently defined disorders. Fortunately, at least from a research point of view, DSM-IV (American Psychiatric Association 1994) did not introduce much change in classifying Axis II disorders.

Pharmacological treatment studies of personality disorders have assessed to varying degrees the comorbid Axis I or Axis II disorders that may be affecting treatment outcome. Also, personality disorders, particularly those of Cluster B, can notoriously differ in how they manifest at differing points in time. For example, BPD patients can be much more or less symptomatic, depending on a variety of environmental factors. Therefore, the traditional 8- to 12-week trial design that establishes a very-short-term baseline and then measures short-term change to an arbitrary endpoint may not be as ideally suited for studying Axis II as it is for Axis I disorders. Trials that use a more broadly defined

baseline, or examine more long-term change across multiple time points, might be more suited to studying Axis II disorders.

Finally, the choice of instruments used to measure Axis II change is critical. Traditionally, these are directly borrowed from Axis I studies, such as the Hamilton Rating Scale for Depression and the Hamilton Anxiety Scale. However, other types of scales measuring less tightly Axis I bound symptoms and concepts such as mood intensity, mood lability, parasuicidal tendencies, aggressive outbursts, and subtle cognitive distortions may be better suited to accurately track Axis II symptomatology. A good example is the Overt Aggression Scale (Coccaro et al. 1991; Yudofsky et al. 1986), which measures and quantifies various types of verbally and physically aggressive behaviors against the self, objects, and others. It is currently widely used in Axis II treatment trials and had no good analog prior to its conception, exemplifying the dimensional approach to personality disorder pathology. Just as important, symptom scales are typically used in Axis II treatment studies rather than measures of character such as defenses, self-concept, personality organization, and interpersonal relationships. Character measures have been pervasively absent from trials to date, and we hope that they will become more prevalent in future studies.

Overview of the Chapter

In this chapter, we review the existing medication trials for the treatment of personality disorders. The chapter is organized by personality disorder clusters, beginning with Cluster B, which has by far the largest number of studies, and followed by Clusters A and C, in which the much fewer existing studies partly overlap with those in Cluster B. We take this pragmatic approach in presenting the treatment studies because the large majority of them selected subjects by personality disorder diagnosis as the major inclusion criterion, although in reviewing these studies, it is always useful to keep in mind the target symptom dimensional approach. Following these sections, the chapter ends with a section on Axis I comorbidity, in which three pertinent questions are addressed: 1) How does the presence of Axis II comorbidity affect the likelihood of medication treatment for Axis I conditions? 2) What is the compliance rate with such treatment? and 3) What is the likelihood of this treatment being efficacious?

PHARMACOTHERAPY FOR CLUSTER B PERSONALITY DISORDERS

By far the most extensive literature on pharmacological treatment of Cluster B, or any Axis II disorders for that matter, refers to BPD. The symptom clusters typically targeted in this condition, although varying from trial to trial and in instruments used, are dysregulated impulsivity and aggression, affective lability and hyperreactivity, cognitive-perceptual disorganization, anxiety, and dissociation. Dysregulation of impulses and affective instability are widely viewed as the hallmark symptoms of BPD. The remaining symptom clusters are examined less systematically in BPD studies—for example, when there is a focus on psychotic spectrum or trauma spectrum pathology.

Summary of Medication Trials

Conventional Antipsychotics

Cognitive-perceptual symptoms, such as paranoia, perceptual aberrations, and subtle thought disorder, although not figuring as prominently in the diagnosis of Cluster B as in Cluster A personality disorders, are definitely present in at least a subgroup of BPD patients, especially under periods of stress and decompensation. The presence of such target symptoms, more prominent in the older BPD trials that included schizotypal subgroups of patients, was the impetus for the early neuroleptic trials. Studies from the late 1970s and early 1980s began to report some efficacy of low-dose neuroleptics in treating BPD, although these studies were not placebo controlled (Brinkley et al. 1979; Leone 1982).

Serban and Siegel (1984) reported on a large trial of 52 outpatients with personality disorders (46

completers: 16 with BPD, 14 with schizotypal personality disorder, 16 with both) treated for 12 weeks in a randomized, double-blind design with thiothixene 9.4 mg/day or haloperidol 3 mg/day (mean dosages). Of the total subjects, 84% showed moderate to marked improvement. The main symptoms that improved were cognitive disturbance, derealization, ideas of reference, anxiety, depression, self-esteem, and social functioning, suggesting that medicating target symptoms may have a wide-reaching effect. Outcome did not vary by borderline or schizotypal diagnosis. In another study (Montgomery and Montgomery 1982), patients with personality disorders, mostly borderline, presenting acutely with a suicide attempt and with histories of at least two prior attempts were treated with a low-dose depot neuroleptic (flupenthixol 20 mg every 4 weeks) or placebo. The neuroleptic was highly effective in reducing suicide attempts at 4–6 months of treatment. Shortly after and for the next decade, several placebo-controlled, randomized trials were published examining conventional antipsychotics in the treatment of BPD and comparing these agents with other classes of medications such as antidepressants, mood stabilizers, and benzodiazepines.

Goldberg et al. (1986) studied 50 outpatients (17 with BPD, 13 with schizotypal personality disorder, 20 with both) with a bias toward psychotic presentation: at least one psychotic symptom was required for inclusion. Subjects were treated for 12 weeks with thiothixene (average dosage = 9 mg/day) or placebo. Thiothixene was significantly better than placebo in treating psychosis (especially for greater symptom severity at baseline), obsessive-compulsive symptoms, and phobic anxiety, but not depression. The results suggested narrow efficacy, because total scores for borderline pathology, schizotypal pathology, and global assessment did not change. When the results were analyzed by diagnosis, the pure BPD subgroup showed the smallest medication effect, implying that neuroleptics may have target specificity for psychotic spectrum symptoms.

Another study, however, suggested that low-dose neuroleptics have a more global effect in treating BPD (Soloff et al. 1986, 1989). Ninety acutely hospitalized inpatients (35 with BPD, 4 with schizotypal personality disorder, 51 with both) were treated for 5 weeks with haloperidol (average dosage = 5 mg/day), amitriptyline (average dosage = 150 mg/day), or placebo. Haloperidol was found to have a broad-spectrum effect in symptom domains, including schizotypal, affective, and impulsive-behavioral, and was superior to amitriptyline in all areas with the exception of a comparable weak antidepressant effect. As in the Goldberg et al. (1986) study, more severe psychotic spectrum symptoms predicted a better response to haloperidol, although overall improvement was still modest.

However, these results were not replicated by the same investigator group in a subsequent large study with a very similar design, consisting of 108 consecutively admitted inpatients (42 with BPD, 66 with BPD and schizotypal personality disorder) treated for 5 weeks with haloperidol, the monoamine oxidase inhibitor (MAOI) phenelzine, or placebo (Soloff et al. 1993). This study failed to replicate efficacy for haloperidol (average dosage = 4 mg/day), with the exception of some measures of overt hostile or aggressive behavior. The investigators attributed this discrepancy to the presence of more severely ill psychotic spectrum patients in the earlier studies and suggested that in less impaired BPD populations, low-dose neuroleptics had little to contribute and were poorly tolerated in terms of side effects. The above acute treatment study was extended into a 16-week outpatient continuation trial with 54 continuing participants (Cornelius et al. 1993), which again yielded essentially negative results. Haloperidol was effective only in treating irritability, and two-thirds of the subjects dropped out.

Another frequently cited medication trial in BPD is a double-blind, placebo-controlled comparison of the typical antipsychotic trifluoperazine (average dosage = 8 mg/day), the benzodiazepine anxiolytic alprazolam (average dosage = 5 mg/day), the anticonvulsant and mood stabilizer carbamazepine (average dosage = 820 mg/day), and the MAOI tranylcypromine (average dosage = 40 mg/day) (Cowdry and Gardner 1988). This study found very modest effects for neuroleptic treatment. Trifluoperazine was only associated with a trend toward lessened behavioral dyscontrol, whereas

alprazolam led to paradoxical disinhibition and worsening of severe behavioral dyscontrol. Psychotic-like symptoms were not assessed. Conventional antipsychotic studies in BPD are summarized in Table 61–1.

TABLE 61–1. Summary of medication treatment trials with antipsychotics in borderline personality disorder (BPD)

Study	Subjects	Antipsychotic(s)	Other agent(s)	Duration	Outcome
Typical antipsychotics					
Montgomery and Montgomery 1982	30 BPD	Depot flupenthixol	Placebo	4–6 months	Decreased suicide attempts
Serban and Siegel 1984	16 BPD, 14 SPD, 16 both	Thiothixene, haloperidol	—	12 weeks	Improvement on multiple domains
Goldberg et al. 1986	17 BPD, 13 SPD, 20 both	Thiothixene	Placebo	12 weeks	Decreased psychosis, anxiety
Soloff et al. 1986, 1989	35 BPD, 4 SPD, 51 both	Haloperidol	Amitriptyline, placebo	5 weeks	General improvement
Cowdry and Gardner 1988	16 BPD	Trifluoperazine	Alprazolam, carbamazepine, tranylcypromine, placebo	6-week crossover	Minimal decrease in behavioral dyscontrol; psychoticism not measured
Soloff et al. 1993	42 BPD, 66 BPD and SPD	Haloperidol	Phenelzine, placebo	5 weeks	Largely ineffective
Cornelius et al. 1993	Continuation of above study			16-week extension	
Atypical antipsychotics					
Frankenburg and Zanarini 1993	15 refractory BPD	Clozapine	—	2–9 months	33% overall improvement
Schulz et al. 1998	BPD	Risperidone	Placebo	8 weeks	Modest improvement, no better than placebo
Schulz et al. 1999	11 BPD (7 also SPD)	Olanzapine	—	8 weeks	General modest to moderate improvement
Zanarini and Frankenburg 2001	28 BPD	Olanzapine	Placebo	6 months	Decreased anger, paranoia, anxiety, interpersonal sensitivity
Rocca et al. 2002	15 BPD with marked aggression	Risperidone	—	8 weeks	Decreased aggression, improved global functioning

Study	Subjects	Antipsychotic(s)	Other agent(s)	Duration	Outcome
Villeneuve and Lemelin 2005	23 BPD	Quetiapine	—	12 weeks	Improved impulsivity, other measures, and global function
Bellino et al. 2006	14 BPD	Quetiapine	—	12 weeks	Improvement especially for impulsiveness/aggressiveness
Perrella et al. 2007	29 BPD	Quetiapine	—	12 weeks	Improvement especially in aggression and low mood
Schulz et al. 2007	314 BPD	Olanzapine 2.5–20 mg/day	Placebo	12 weeks	No difference in overall symptom improvement between groups
Zanarini et al. 2007	451 BPD	Low-dose olanzapine (2.5mg/day), moderate-dose olanzapine (5–10 mg/day)	Placebo	12 weeks	Greater overall improvement on moderate-dose olanzapine compared with two other groups

Note. SPD = schizotypal personality disorder.

Atypical Antipsychotics

The question of efficacy of atypical antipsychotics in BPD has received growing attention (see Table 61–1), and earlier smaller trials have now been followed by larger studies. An open trial of clozapine in 15 severely disturbed patients with refractory BPD and pronounced psychotic symptoms reported an overall 33% improvement during a 2- to 9-month treatment (Frankenburg and Zanarini 1993). Given the weekly monitoring and the common compliance difficulties of BPD patients, this antipsychotic is clearly not the optimal choice for the average patient. A case report noted partial to good response to aripiprazole treatment in 2 out of 3 patients (Mobascher et al. 2006). A small 8-week placebo-controlled risperidone trial in BPD reported similar modest symptomatic improvement in the two treatment groups (Schulz et al. 1998). An open-label trial of risperidone in 15 BPD outpatients with prominent histories of aggressive behavior and no current major Axis I disorders, using a final mean dosage of 3.3 mg/day, reported a marked reduction in aggression, along with a reduction in depressive symptoms and improved global functioning (Rocca et al. 2002).

To date, there are three published quetiapine treatment trials in BPD, all open-label. In one 12-week trial in 23 outpatients, at a mean dosage of 250 mg/day, impulsivity significantly improved, as did most other outcome measures and global functioning (Villeneuve and Lemelin 2005). Another 12-week trial in 14 outpatients employed an average dosage of about 300 mg/day and reported significant improvement in various symptom domains, particularly impulsiveness/aggressiveness (Bellino et al. 2006). The third open trial followed 29 outpatients for 12 weeks, at a higher average dosage of 540 mg/day, and reported a highly significant improvement in a number of BPD features, including aggression and low mood; transient thrombocytopenia occurred in 2 patients (Perrella et al. 2007). Finally, a case report described a marked improvement in severe self-mutilation in two BPD patients treated with quetiapine (Hilger et al. 2003).

An 8-week open trial examined the efficacy of olanzapine (average dosage = 8 mg/day) in 11 BPD outpatients with comorbid dysthymia, 7 of whom also had schizotypal personality disorder, and reported moderate significant improvement in all symptom domains (Schulz et al. 1999). In a small controlled olanzapine trial of 28 women with BPD (Zanarini and Frankenburg 2001), longer duration of treatment was undertaken for 6 months, a time frame more reflective of clinical reality, at a mean end

dose of 5.3 mg/day. Olanzapine was found to be significantly better than placebo in decreasing anxiety, paranoia, anger/hostility, and interpersonal sensitivity, but not depression.

More recently, two much larger randomized, controlled multicenter trials have yielded mixed findings on the efficacy of olanzapine in treating BPD. One 12-week study used flexibly dosed olanzapine (range 2.5–20 mg/day) versus placebo in 314 outpatient participants with moderate disorder severity, and although both treatment groups significantly improved during treatment, there was no difference in overall change between the two groups ($P = 0.66$), with response rates of 65% for olanzapine and 54% for placebo group (Schulz et al. 2007). The second 12-week study of 451 BPD participants was overall similar in design and illness severity but differed in using two fixed dosages of olanzapine, low (2.5 mg/day) and moderate (5–10 mg/day), versus placebo (Zanarini et al. 2007). Treatment with the higher olanzapine dose resulted in significantly greater overall improvement than the lower dose ($P = 0.018$) and the placebo ($P = 0.006$), with response rates of 74%, 60%, and 58%, respectively. Furthermore, both olanzapine-treated groups showed significantly greater improvement on irritability, suicidality, and family life functioning relative to placebo. Adverse events more common on olanzapine included somnolence and weight gain (3.2 kilograms for the higher dose).

Antidepressants

Tricyclic antidepressants (TCAs) have a limited role in treating BPD (Soloff et al. 1986, 1989). The few MAOI trials that have been conducted have yielded mixed results. Soloff et al. (1993) and Cornelius et al. (1993) found that phenelzine had only modest efficacy in BPD and was superior to placebo only against anger and hostility, but not in measures of depression, atypical depression, psychoticism, impulsivity, or global borderline severity. The investigators speculated that the short duration of treatment, the use of suboptimal phenelzine dosing (average dosage = 60 mg/day), and the fact that the atypical depression characteristics known to be responsive to MAOIs were not highly prominent in the patient samples may have contributed to these studies' failure to show efficacy for phenelzine. In contrast, a crossover placebo-controlled study of four classes of medications in BPD (Cowdry and Gardner 1988) found that the MAOI tranylcypromine was significantly superior to placebo, according to both clinicians and patients, in global ratings and in most domains that were measured, including depression, anxiety, anger, rejection sensitivity, impulsivity, and suicidality. This finding was more in accordance with an earlier report of phenelzine efficacy in BPD patients, all of whom had concurrent atypical depression (Parsons et al. 1989).

Regardless of efficacy, both TCAs and MAOIs pose serious overdose and dangerous adverse effect risks that are of particular concern in this unstable, impulsive population. Investigations of newer antidepressants in treating BPD appear more promising. Preliminary reports in small open trials first suggested that the selective serotonin reuptake inhibitor (SSRI) fluoxetine at dosages ranging from 20 to 60 mg/day might be beneficial in treating depression and impulsive aggression in BPD (Coccaro et al. 1990; Cornelius et al. 1991; Norden 1989). A larger open trial (Markovitz et al. 1991) involved 22 patients with BPD or schizotypal personality disorder treated for 12 weeks with high-dose fluoxetine (80 mg/day). There was a 74% decline in self-mutilation, as well as an overall improvement in depressive symptoms, obsessive-compulsive symptoms, anxiety, interpersonal sensitivity, psychoticism, and paranoia. In a comparable open trial by the same group (Markovitz 1995), 23 BPD patients were treated openly for an initial 12-week period with sertraline 200 mg/day, and about half showed improvement in self-injurious behavior, anxiety, depression, and suicidality. Of note, half of the responders had previously failed to respond to fluoxetine, underlining the usefulness of trying more than one SSRI in this population, given the variability of responses across SSRIs. The trial was continued to a 1-year duration, and dosages in nonresponders were increased to more than 300 mg/day. By the completion of the study, on average, depression had decreased by 56% and self-injurious episodes had decreased by 93%. In another small open trial of sertraline in nine patients with personality disorders, dosages of 100–200 mg/day resulted in a decrease of impulsive

aggression over 8 weeks (Kavoussi et al. 1994).

Subsequently, three controlled trials of SSRIs in borderline spectrum patients have been described. In a small double-blind trial, 17 BPD patients were randomly assigned to high-dose fluoxetine (80 mg/day) or placebo for 14 weeks. A statistically significant improvement was seen in the fluoxetine group, compared with placebo, on all measures used, including global symptomatology, anxiety, and depression (Markovitz 1995). A larger study randomly assigned 27 patients with borderline disorder or traits, at the milder end of the severity spectrum and without current major depression, to fluoxetine (average dosage = 40 mg/day) or placebo (Salzman et al. 1995). The main finding after 12 weeks of treatment was a significantly greater decrease in anger and depression with fluoxetine, despite a pronounced placebo response. Finally, in the largest trial reported (Coccaro and Kavoussi 1997), the effects of fluoxetine were investigated over a 12-week period in 40 subjects with personality disorder with marked impulsive aggression as the major entry criterion and without current major depression. About half of the subjects met Cluster B criteria (one-third of the total had BPD), 40% met Cluster C criteria, and 28% met Cluster A criteria. Compared with placebo, fluoxetine at dosages of 20–60 mg/day led to a consistent and significant decrease in aggression and irritability and in global improvement apparent by the second month of treatment, and this effect was irrespective of changes in depression or anxiety.

In addition to SSRIs, newer antidepressants have been tried in BPD. In an open trial of the serotonin–norepinephrine reuptake inhibitor (SNRI) venlafaxine, 45 subjects were entered and 39 completed a 12-week treatment with an average dosage of 315 mg/day (Markovitz and Wagner 1995). A highly significant overall reduction of 41% occurred on a scale of global symptomatology. Of the 7 patients who were self-injurious at baseline, only 2 remained self-injurious at the end of treatment. Although the study was not placebo controlled, this was a fairly large trial, and the results appear promising. Studies of antidepressant treatment in BPD are summarized in Table 61–2.

TABLE 61–2. Summary of medication treatment trials with antidepressants in borderline personality disorder (BPD)

Study	Subjects	Antidepressant(s)	Other agent(s)	Duration	Outcome
Soloff et al. 1986, 1989	35 BPD, 4 SPD, 51 both	Amitriptyline	Haloperidol, placebo	5 weeks	Minimally effective and only for depression
Soloff et al. 1993	42 BPD, 66 BPD and SPD	Phenelzine	Haloperidol, placebo	5 weeks	Modest efficacy, better than placebo
Cornelius et al. 1993	Continuation of above study			16-week extension	Only for hostility/anger
Cowdry and Gardner 1988	16 BPD	Tranylcypromine	Alprazolam, carbamazepine, trifluoperazine, placebo	6-week crossover	Decreased depression, anxiety, anger, rejection sensitivity, impulsivity, suicidality
Markovitz et al. 1991	22 BPD or SPD	Fluoxetine	—	12 weeks	Marked decline in self-mutilation, depression, anxiety, interpersonal sensitivity, paranoia
Markovitz 1995	23 BPD	Sertraline	—	12 weeks	Half of subjects showed improvement in self-injury, anxiety, depression, suicidality

Study	Subjects	Antidepressant(s)	Other agent(s)	Duration	Outcome
	Continuation of above study			1 year	Decline in depression 56%, self-injury 93%
Kavoussi et al. 1994	9 personality disorder with impulsive aggression	Sertraline	—	8 weeks	Decreased impulsive aggression
Markovitz 1995	17 BPD	Fluoxetine	Placebo	14 weeks	Global improvement on all measures
Salzman et al. 1995	27 BPD or BPD traits	Fluoxetine	Placebo	12 weeks	Decreased anger, depression
Coccaro and Kavoussi 1997	40 impulsive-aggressive personality disorder (one-third BPD), no major depression	Fluoxetine	Placebo	12 weeks	Marked decrease in aggression and irritability irrespective of changes in anxiety/depression
Markovitz and Wagner 1995	45 BPD	Venlafaxine	—	12 weeks	40% global improvement, less self-injury

Note. SPD = schizotypal personality disorder.

Mood Stabilizers

Mood stabilizers also have emerged as highly promising in treating BPD. The literature on lithium is unfortunately limited to older studies but looks promising. Most studies examined the effects of lithium on aggression in mentally retarded or violent inmate populations and reported some efficacy (reviewed by Wickham and Reed 1987). More directly relevant to BPD, an older study had first documented the efficacy of lithium in treating mood lability (other symptoms were not measured) in a 6-week placebo-controlled trial of 21 subjects with "emotionally unstable character disorder" (Rifkin et al. 1972). Description of the characteristics of this disorder, such as mood swings, overreactivity, impulsivity, and chronic maladaptive behaviors, clearly overlaps with current BPD criteria, although these patients may have had a bipolar variant. Finally, a single small controlled study examined lithium in subjects meeting clear BPD criteria (Links et al. 1990). Seventeen subjects received 6 weeks each of lithium, the TCA desipramine, and placebo in a randomized crossover design, and 10 completed at least two medication trials. Neither medication was better than placebo for depressive symptoms, but lithium resulted in a significant decrease in anger and suicidality according to clinician, but not patient, perception. A larger study is clearly warranted but has not been done.

Anticonvulsants are used more widely than lithium in treating BPD. Cowdry and Gardner (1988) found that carbamazepine led to a dramatic and highly significant decrease in behavioral dyscontrol but had much more modest effects on mood, and patients subjectively did not feel better while taking it. This was a 6-week double-blind, placebo-controlled crossover design, comparing alprazolam (average dosage = 5 mg/day), carbamazepine (average dosage = 820 mg/day), trifluoperazine (average dosage = 8 mg/day), and tranylcypromine (average dosage = 40 mg/day) (Cowdry and Gardner 1988). Subjects were 16 female outpatients with BPD, with additional inclusion criteria of presence of prominent behavioral dyscontrol and absence of current major depression. However, another carbamazepine study, involving 20 inpatients with BPD without concurrent depression or concomitant

medications, yielded negative results (De La Fuenta and Lotstra 1994). After 4 weeks of treatment at standard therapeutic drug levels, carbamazepine was no better than placebo in treating depression, behavioral dyscontrol, or global symptomatology.

More recently, anticonvulsant trials have focused on valproate and, to a lesser extent, on the newer anticonvulsants. In one open trial, 11 patients with BPD were treated openly with valproate for 8 weeks, attaining blood levels of 50–100 μg/mL, and 8 patients completed the trial (Stein et al. 1995). Half of the completers were rated as overall responders, with significant decreases in depression, anxiety, anger, impulsivity, rejection sensitivity, and irritability. The trial was summarized as modestly helpful, and larger controlled studies were called for to establish valproate efficacy in BPD. In another open-label trial, 20 BPD patients were treated for 12 weeks with extended-release valproate, leading to significant overall improvement and decline in irritability and aggression (Simeon et al. 2007). In another small but placebo-controlled trial, 16 outpatients with BPD were treated for 10 weeks with valproate or placebo (Hollander et al. 2001). Global improvement was significant by two measures in patients treated with valproate, but the small sample size and dropout rate precluded statistically significant findings. In another controlled valproate study, efficacy was examined in 30 women with comorbid BPD and bipolar II disorder over 6 months of treatment (Frankenburg and Zanarini 2002). Valproate at an average dosage of 850 mg/day (with blood levels ranging between 50 and 100 μg/mL) was well tolerated and resulted in significant improvement in interpersonal sensitivity, hostility/anger, and aggression compared with placebo.

More importantly, there is now a large placebo-controlled multicenter trial of valproate focusing on the treatment of impulsive aggression in Cluster B personality disorders (Hollander et al. 2003). Ninety-one outpatients selected for the presence of prominent impulsive aggression and absence of bipolar I disorder or current major depression were randomly assigned to 12 weeks of treatment with placebo or valproate, at an average end dosage of 1,400 mg/day with an end mean blood level of 66 μg/mL. About 10% were taking concomitant stable doses of antidepressants, and there was an approximately equal dropout rate of almost half of the subjects in each group. Valproate was well tolerated overall, with 17% of the subjects discontinuing for valproate-related adverse events. The main finding of the study was a significant decrease in impulsive aggression in the last month of treatment, reflected in significantly greater than placebo declines in overall aggression, including verbal assault, assault against objects, and assault against others, and in overall irritability. When the BPD subgroup of the above study was examined separately (Hollander et al. 2005), it was found that divalproex was indeed superior to placebo in reducing impulsive aggression in this subgroup. Divalproex-treated patients responded better as a function of higher baseline trait impulsivity symptoms and state aggression symptoms. These two effects appeared to be independent of one another, while baseline affective instability did not influence differential treatment response.

With respect to the newer anticonvulsants, there is a report of a small open trial of lamotrigine, 75–300 mg/day, while concomitant psychotropic medications were tapered off, in eight patients with BPD without concurrent major depression (Pinto and Akiskal 1998). Two subjects were discontinued secondary to adverse events or noncompliance, and three did not respond. The remaining three were described as robust responders, with a marked increase in their overall level of functioning; a cessation of impulsive behaviors such as promiscuity, substance abuse, and suicidality; and maintenance of response at 1-year follow-up. We can probably expect further trials of new anticonvulsants in BPD. Medication trials of mood stabilizers in BPD are summarized in Table 61–3.

TABLE 61–3. Summary of medication treatment trials with mood stabilizers in borderline personality disorder (BPD)

Study	Subjects	Mood stabilizer(s)	Other agent(s)	Duration	Outcome

Study	Subjects	Mood stabilizer(s)	Other agent(s)	Duration	Outcome
Rifkin et al. 1972	21 emotionally unstable character disorder	Lithium	Placebo	6 weeks	Decreased mood lability
Cowdry and Gardner 1988	16 BPD	Carbamazepine	Trifluoperazine, tranylcypromine, alprazolam, placebo	6-week crossover	Marked decrease in behavioral dyscontrol
Links et al. 1990	17 BPD	Lithium	Desipramine, placebo	6-week crossover	Decreased anger and suicidality
De La Fuenta and Lotstra 1994	20 BPD without depression	Carbamazepine	Placebo	4 weeks	No effect for depression, behavioral dyscontrol, global symptoms
Stein et al. 1995	11 BPD	Valproate	—	8 weeks	Modest benefit, half responders, less depression, anxiety, anger, impulsivity, rejection sensitivity
Pinto and Akiskal 1998	8 BPD without depression	Lamotrigine	—	1 year	Two discontinued; three robust global responders with decreased impulsivity and suicidality
Frankenburg and Zanarini 2002	30 BPD	Valproate	Placebo	6 months	Significant improvement in hostility, anger, aggression, interpersonal sensitivity
Hollander et al. 2003	91 impulsive-aggressive Cluster B	Valproate	Placebo	12 weeks	Significant decrease in impulsive aggression
Simeon et al. 2007	20 BPD	Valproate extended release	—	12 weeks	Overall improvement, decreased irritability and aggression

Other Medications

Another class of medications for which very limited data exist on treating BPD is the opioid antagonists. A more extensive literature supports the efficacy of naltrexone in treating impulsive addictive behaviors such as alcoholism and gambling, and therefore naltrexone would be a consideration in borderline patients with these types of problems. An open trial of naltrexone at daily dosages of 100–400 mg in 15 women with BPD found that it led to a significant decrease in dissociative symptoms and flashbacks over a course of treatment of at least 2 weeks (Bohus et al. 1999).

Conclusions and Treatment Guidelines

In conclusion, several open and controlled pharmacological treatment trials of BPD have been conducted. Interpretation of the findings is somewhat complicated by the diversity of patient

presentations at treatment entry, including inpatient or outpatient status; overall severity of baseline pathology; presence of comorbid personality disorders; presence or absence of major depression, including atypical symptoms; emphasis on varying symptomatology, such as psychoticism or impulsive aggression; and use of a wide range of change measures. In addition, some of the core features of the disorder, such as identity diffusion, interpersonal vicissitudes, and primitive defensive structure, were never examined, and thus the assumption that these features are less medication responsive has not been empirically proven. As mentioned earlier, it is not unreasonable to assume that stabilization and alleviation of dysregulated affect, cognition, and impulses could have a beneficial effect on "deeper" aspects of character structure. Furthermore, concomitant psychotherapy is rarely mentioned as an exclusion criterion in the BPD medication trials, and clinical knowledge of these populations makes it reasonable to assume that it must have commonly co-occurred, even if of a general exploratory and supportive nature and not specifically geared to the structured treatment of the condition. We therefore cannot underestimate the potential influence of general placebo effects and concomitant therapies in many of these studies, and medications continue to be viewed as adjuvant features of treating patients with Cluster B disorders.

Notwithstanding, it is reasonable to conclude that three classes of medications emerge as the most useful in treating BPD: serotonin reuptake inhibitors, mood stabilizers, and atypical antipsychotics. Fluoxetine, valproate, and olanzapine are the three best-studied medications to date regarding efficacy. Comparison trials of these three classes of medications, including combination strategies, have not been reported and would be of great interest in the future.

Dosing guidelines are also not entirely clear because most trials aim to minimize possible undertreatment and tend to use relatively high dosages. Therefore, SSRIs may be efficacious at lower dosages than the 60 or 80 mg/day fluoxetine target dosages that have been studied. There are also no guidelines for targeted blood levels of valproate in treating BPD, although a recent large trial reported efficacy at a mean endpoint blood level of 66 μg/mL (Hollander et al. 2003). For olanzapine, it appears that moderate doses are more effective than low doses (Zanarini et al. 2007). In clinical settings, it makes sense to start with lower doses because these are generally better tolerated and gradually increase the dosage while carefully monitoring response to increasing dose. Symptoms of the disorder are often chronic and by their nature considerably fluctuating; thus, the effect of each medication and dose can be more reliably assessed over longer rather than shorter durations.

With respect to specific target symptoms, certain algorithms can be extrapolated from the existent trials and have been proposed on the basis of the types of symptoms that are most prevalent in each patient and the degree of response to the various medication pathways (American Psychiatric Association 2001; Soloff 1998). These algorithms give useful practical guidance, although they tend to become quickly outdated with findings of new trials. On the basis of the existent algorithms in the literature and modifying them according to the results of the latest medication trials, we propose a medication treatment approach outline for BPD as summarized in Table 61–4.

TABLE 61–4. Psychopharmacological treatment guidelines for borderline personality disorder

If most prominent symptoms are depression, interpersonal sensitivity, and impulsivity and aggression

1. Start with selective serotonin reuptake inhibitor (SSRI) (or related antidepressant).
2. *If good response,* maintain.

   If partial response, add mood stabilizer.

   If no response, switch to mood stabilizer.
3. *If significant residual anger, anxiety, dyscontrol,* add atypical antipsychotic.

If most prominent symptoms are mood lability, impulsivity and aggression, and family history of bipolar spectrum

1. Start with mood stabilizer (valproate; carbamazepine or lithium as alternatives).
2. *If good response,* maintain.

   If partial response, add mood stabilizer.

   If no response, switch to mood stabilizer.
3. *If significant residual anger, anxiety, dyscontrol,* add atypical antipsychotic.

If most prominent symptoms are paranoia, psychoticism, hostility, and overwhelming anxiety

1. Start with atypical antipsychotic (olanzapine and risperidone most studied).
2. *If good response,* maintain.

   If partial response, add SSRI or mood stabilizer.

   If no response and minimal mood symptoms, switch to typical antipsychotic.

Almost all Cluster B personality disorder trials have focused primarily on BPD. Although some of these trials, as individually mentioned in the overview above, included mixed samples of Cluster B participants, they did not present separate analyses for non-BPD diagnoses. Therefore, the general principle to follow in treating these other disorders would be to target symptom clusters with medications as per the guidelines developed above for BPD. In general, narcissistic and histrionic personality disorders are not characterized by the severe degree of either mood lability or impulse dyscontrol encountered in BPD, but in individuals in whom such features are more prominent or problematic, medication trials can be attempted. With regard to antisocial personality disorder, the general treatment guideline is that individuals who meet full criteria for the disorder are generally treatment noncompliant and nonresponsive. Very few pharmacological studies have been done in patients with antisocial personality disorder (Coccaro 1993), and those closest to showing at least temporary benefits are some of the earlier lithium studies that reported decreased impulsive-aggressive behavior in prison inmates (Wickham and Reed 1987). More recently, a report on four antisocial personality disorder inpatients in a maximum-security facility found decreases in impulsivity, hostility, aggressiveness, irritability, and rage reactions with quetiapine treatment at dosages of 600–800 mg/day (Walker et al. 2003). Generally, borderline patients who have some antisocial traits are more responsive to medication treatment than purely antisocial patients. Recent studies with the mood stabilizer valproate suggest that subjects with antisocial personality disorder are less responsive to the pharmacotherapy than are subjects with other Cluster B personality disorders (Hollander et al. 2003). It also has been found that borderline patients are significantly more likely than antisocial personality disorder patients to have received adequate medication trials, including anxiolytics and antidepressants (Zanarini et al. 1988).

PHARMACOTHERAPY FOR CLUSTER A PERSONALITY DISORDERS

Cluster A personality disorders are characterized by cognitive distortions, perceptual distortions, mild thought disorder, constricted affectivity, and interpersonal mistrust and distance. Schizotypal personality disorder is the prime example of all these symptom clusters, whereas in paranoid and schizoid personality disorders, the cognitive-perceptual and thought disorder disturbances are not prominent. Cluster A symptoms are reminiscent of both the positive and the negative symptoms of schizophrenia, and dopaminergic dysregulation has been postulated to underlie them (Siever and Davis 1991). Schizotypal personality disorder is by far the most extensively investigated disorder of the cluster in terms of biological underpinnings (Siever 1985; Siever et al. 1990), relation to Axis I as a schizophrenia spectrum disorder (Asarnow et al. 2001; Kendler et al. 1994), and pharmacological treatment trials. All the treatment trials to date, however, have included subjects typically with BPD or

with mixed personality disorders. They have been presented already in the Cluster B section, and we summarize them again here with respect to schizotypy findings. We are not aware of any medication trials examining specifically paranoid or schizoid personality disorder.

Serban and Siegel (1984) treated a sample of patients, one-third of whom had schizotypal personality disorder and one-third of whom had schizotypal personality disorder and BPD, with either thiothixene or haloperidol, without placebo, and found marked improvement in psychotic spectrum symptoms. Goldberg et al. (1986) treated a similar sample with thiothixene or placebo and found a significant improvement in psychotic symptoms with thiothixene that was more pronounced in the patients with the schizotypal rather than the borderline diagnosis. Soloff et al. (1986, 1989), in a sample containing a sizable proportion of combined schizotypal personality disorder and BPD patients, found significantly better efficacy for haloperidol compared with placebo for schizotypal symptoms but were not able to replicate this finding in a subsequent haloperidol trial with similar diagnoses (Soloff et al. 1993). They speculated that their failure to replicate might have been because the later trial included a less disturbed group of subjects with less prominent psychotic symptoms.

With regard to the treatment of schizotypy with atypical antipsychotics, Schulz et al. (1999) reported improvement in psychotic symptoms in a small group of patients who received olanzapine, most of whom had schizotypal personality disorder that was comorbid with BPD. There is one published randomized, placebo-controlled trial of an atypical antipsychotic focusing exclusively on schizotypal personality disorder, which found risperidone to be significantly more efficacious than placebo (Koenigsberg et al. 2002). In this 9-week study in 25 schizotypal personality disorder patients, with low incidence of comorbid depression or BPD, low-dose risperidone was used, titrated up from 0.25 to 2 mg/day. Active medication resulted in a significantly greater decrease in negative and positive symptoms compared to placebo, and side effects were generally well tolerated.

With regard to the effect of antidepressants on schizotypal personality disorder, Markovitz et al. (1991) conducted an open trial of fluoxetine in patients with BPD and schizotypal personality disorder (proportions of each unspecified) and reported improvement in psychoticism and paranoia, among numerous other symptoms. Although the results were not analyzed with respect to diagnosis, it is notable that no worsening of psychotic spectrum symptoms was found. This finding is difficult to interpret in that improved paranoia could be consequent to better affective regulation in subjects with prominent borderline traits. Of note, an older trial reported increased hostility and paranoia in a subgroup of patients treated with the TCA amitriptyline (Soloff et al. 1986, 1989). Finally, a large trial of fluoxetine that found significant benefits for impulsive aggression across Axis II disorders (Coccaro and Kavoussi 1997) included 28% Cluster A subjects, but results did not focus on psychotic spectrum symptoms and were not presented separately by cluster.

In summary, the limited trials of Cluster A disorders suggest, not surprisingly, that the medications of choice are conventional antipsychotics. Given the probable need for long-term treatment of the chronic, stable psychotic spectrum symptoms in these populations, the better safety profile of atypical antipsychotics with regard to tardive dyskinesia suggests that they should be tried first, although more data exist in the literature to date examining conventional neuroleptics. Finally, in subjects with mixed traits and prominent additional affective or impulsive symptoms, SSRIs appear to cause no worsening of psychosis and may be of some adjuvant benefit.

PHARMACOTHERAPY FOR CLUSTER C PERSONALITY DISORDERS

Anxiety and behavioral inhibition are the main symptoms that characterize individuals with Cluster C personality disorders, although the focus of the anxiety varies across disorders. It centers on social interaction in avoidant personality disorder, need for control of uncertainty in obsessive-compulsive personality disorder, and conflicts surrounding autonomy in dependent personality disorder. The medication trials in these disorders are very limited to date and are summarized below. In addition,

limited indirect information and insights can be gauged from studies either of related Axis I disorders or of personality traits or dimensions that are characteristic of the Cluster C personality disorders.

Avoidant personality disorder has received the most attention in terms of pharmacological treatment of the Cluster C disorders because it is often viewed as lying on a continuum with Axis I social phobia. Clinically, it can be difficult to distinguish pervasive, generalized social phobia of long-standing duration from avoidant personality disorder. The latter tends to be characterized by deeper interpersonal difficulties, impairments in interpersonal skills, and a very small number of close relationships, which is often not the case even in very socially phobic individuals (Turner et al. 1986). Numerous studies have convincingly shown the efficacy of MAOIs and SSRIs in social phobia, including its generalized subtype. Although, unfortunately, these studies did not report on the presence or change in avoidant personality, they do suggest that these medications may be worth trying in treating the Axis II variant. Indeed, a few open trials and case reports have reported promising findings.

Deltito and Perugi (1986) reported the case of a man with pervasive social phobia and avoidant personality disorder who responded well to phenelzine 45 oceg14 w-7(y)-24(b-41(0w)-29(e)e)-11(b-41(0w)-2

Tyrer 1992).

We are also not aware of studies examining the pharmacological treatment of dependent personality disorder. It has been reported in the presence of comorbid Axis I panic disorder, in particular, that the initial rate of dependent personality traits was to a large extent state related and waned with the treatment of panic over a 3-year period (Noyes et al. 1991).

Finally, one study examined change in core symptoms of Cluster C disorders, as measured by personality inventories in the absence of categorical Axis II assessment, in patients treated pharmacologically for Axis I disorders (Brody et al. 2000). In 37 patients treated with SSRIs for major depression or OCD, an increase in social dominance and a decrease in social hostility were found, irrespective of treatment response for Axis I, supporting the notion that serotonin reuptake inhibitors may be useful to treat avoidant personality traits. Similarly, a decrease in harm avoidance was found with treatment, which was greater in the Axis I treatment responders, again supporting the notion that serotonin reuptake inhibitors may be useful in treating obsessive-compulsive and dependent personality traits. More pharmacological studies using this dimensional approach to symptom change would be of interest in Cluster C personality disorders.

TREATMENT ISSUES IN THE PRESENCE OF AXIS I COMORBIDITY

This section focuses not on the direct treatment of Axis II disorders but rather on the widely asked question of whether the presence of Axis II disorders affects the likelihood of, compliance in, or success of treating major Axis I disorders, primarily depression and anxiety. The literature in this area often shows contradictory results, and lore blends with evidence-based reality. Here we summarize the major empirical findings against the background of a widely espoused belief, not necessarily substantiated by fact, that the presence of personality disorders generally impedes the recognition and successful treatment of Axis I disorders.

A community survey, conducted as part of a 1981 epidemiological study that used DSM-III (American Psychiatric Association 1980) diagnostic criteria, examined the association between Axis I and II disorders and the need for and likelihood of treatment (Samuels et al. 1994). Among subjects with any Axis I disorder, 87% of those with personality disorders were in need of treatment compared with 46% of those without, a highly significant difference. Furthermore, 18% of the subjects with personality disorders were actually receiving treatment compared with 6% of the subjects without. In essence, then, although those with comorbid personality disorders were proportionately more likely to be receiving some type of psychiatric treatment if in need of it, about 80% of the total individuals with personality disorders who were deemed as needing treatment were not receiving it.

The literature is most extensive for depressive disorders. Earlier studies from the 1980s reported that depressed patients with personality disorders were less likely to receive medication treatment (Black et al. 1988; Charney et al. 1981) or received it for shorter periods (Pfohl et al. 1987) than did those without personality disorders. However, Downs et al. (1992) found that patients with Axis II comorbidity were not less likely to receive medications. Based on chart review, they were actually likely to receive greater numbers of medications, especially if they had BPD, than patients without personality disorder. In regard to the question of compliance, patients with major depression who dropped out of controlled medication trials were characterized by a significantly higher prevalence of "image distorting" defense mechanisms, such as projective identification, splitting, omnipotence, and idealization/devaluation (Mullen et al. 1999).

Two review studies have examined the impact of Axis II disorders on the efficacy of pharmacotherapy in depressed patients. A descriptive review study (Mulder 2002) examined more than 50 relevant trials and concluded that better-designed treatment trials were least supportive of an adverse effect of personality pathology on depression outcome. A negative impact of personality on depression treatment was most consistently found for high neuroticism scores, whereas Cloninger's personality

dimensions bore no consistent relation to depression outcome. Similarly, when personality disorders were measured by categorical diagnostic instruments, results among the various studies were quite inconsistent, and the best-designed studies that used structured diagnostic interviews and randomized, controlled designs showed the least effect. A more recent meta-analytic review study (Kool et al. 2005) reported similar findings. When all randomized, controlled trials in adult ambulatory patients with major depression and comorbid personality disorders were examined according to strict methodological criteria, the difference in depression remission rates between the groups with and without Axis II disorders was a mere 3%, a difference neither statistically significant nor clinically pertinent. However, another study reported that acute response of major depressive disorder to electroconvulsive therapy (ECT) was poorer in patients with comorbid BPD than in patients with other or no personality disorders, a finding not accounted for by age, gender, or medication-resistance status (Feske et al. 2004).

Addressing a somewhat different question, a recent 11-year prospective study examined whether the presence of Axis II comorbidity increases the likelihood of major depression recurrence or relapse and found that it did (Khan et al. 2007). In a sample of 168 outpatients receiving long-term treatment with an SSRI, Cluster A, B, and C dimensional personality traits were highly inversely correlated with duration of stability without mood disorder. Similar findings were reported when Axis II pathology was examined categorically; patients without personality disorders remained in remission from depression almost twice as long as did patients with at least one personality disorder.

Less literature exists examining the relation between the treatment of Axis I bipolar disorder and the presence of Axis II personality disorder. A study of 200 bipolar I and II disorder patients examining various factors affecting medication compliance found that personality disorder comorbidity was the factor most strongly associated with poor compliance (Colom et al. 2000). About one-quarter of the subjects had at least one comorbid Axis II disorder, and of these, 17% were assessed as having good compliance, 37% medium compliance, and 44% poor compliance.

Fewer studies have examined the relation between Axis II comorbidity and treatment of Axis I anxiety disorders. A recent report claims to be the first one to examine the amount of psychiatric treatment received in anxiety disorder patients as a function of comorbid personality disorder (Phillips et al. 2001). This large study examined several hundred anxious patients with a variety of Axis I diagnoses: panic disorder, generalized anxiety disorder, social phobia, OCD, posttraumatic stress disorder, and agoraphobia. Despite minor discrepancies between the two time-point assessments (1991 and 1996), the findings were fairly consistent: similar percentages of anxious subjects with and without personality disorders received medication treatment. If medicated, those with personality disorders, and especially those with BPD, were likely to be receiving a greater number of medications, specifically heterocyclic antidepressants. Thus, these investigators found no evidence for medication undertreatment of patients with Axis II comorbidity. They proposed, in reviewing trends in the pertinent literature, that influential biological studies and medication trials of Axis II disorders from the late 1980s and the early 1990s may have led toward a more favorable shift in medicating patients with personality disorders who previously may have been more likely to be assessed as needing only psychotherapy.

CONCLUSION

In this chapter, we reviewed the pharmacological treatment of personality disorders, providing a conceptual framework, highlighting methodological limitations, and summarizing treatment trials to date. Almost all of these trials focused on symptom clusters, such as psychoticism, impulsivity, hostility/aggression, mood instability, and anxiety/inhibition. Trials were largely limited to BPD, although from some trials, additional conclusions can be drawn about other personality disorders in mixed-group study designs or by extrapolation of comparable symptom clusters. It is becoming increasingly established that medication treatment can play a very important role, albeit adjunctive to

psychotherapy, in the treatment of personality disorders. Even if benefits are more modest than those encountered with medication treatment of some Axis I conditions, they can still make a significant contribution to symptom reduction, functional improvement, and overall adaptation. Continued medication trials of Axis II disorders that also focus on broader dimensions of personality, including aspects of character, are eagerly awaited.

patient is of the greatest importance. There should be clear, definable treatment objectives for hospitalization, and the facility in which the patient is hospitalized should be able to meet these needs. Beyond consideration of the patient's welfare, other factors can contribute to the decision of whether to hospitalize a patient (R. I. Simon 1998). These include availability of psychiatric hospital beds and admission authorization by third-party payers. A decrease in funding of mental health services has resulted in a decrease in available inpatient resources. Thus, the clinician must balance the availability of resources with the needs of individual patients. And while third-party payers may limit the ability to admit a patient to a hospital, the onus of providing appropriate care ultimately falls on the clinician.

Once the decision is made to hospitalize a patient, every effort should be made to have this occur on a voluntary basis. This is the first step in establishing therapeutic rapport with patients. The indiscriminate use of involuntary commitments can set up the perception of an adversarial relationship between patients and treatment providers (Olofsson and Jacobson 2001). Patients with chronic, persisting mental illnesses will most likely require multiple hospitalizations in the course of their illness. Avoiding experiences that elicit the perception of being "locked up" against one's will is one way of facilitating the long-term care of the mentally ill patient.

Suicidal State

Suicide is the eleventh leading cause of death in the United States across all age groups. As a public health issue, suicide continues to be a major problem, with a population rate around 11 deaths per 100,000, which has remained invariant over the past four decades. But there are several recent studies that suggest a slight decrease in U.S. suicide rates since selective serotonin reuptake inhibitors (SSRIs) have been introduced. Historically, one of the truly vexing problems in psychiatry is the lack of effect of specific psychiatric treatments on the suicide rate. Several studies have failed to find any association between the availability of psychiatric treatment resources and the suicide rate (Garlow et al. 2002; Lewis et al. 1994).

Predicting imminent suicide in any individual patient is difficult and can provoke significant anxiety in the clinician (Pokorny 1983, 1993). Completed suicide is a rare event, but it has profound effects on both the surviving family members and friends of the victim and the physician and treatment staff (Gitlin 1999; Hendin et al. 2000). There are also potential legal ramifications of a patient's committing suicide if he or she has been in recent contact with psychiatrists and other mental health providers (R. I. Simon 2000).

Recently, a relationship between antidepressant use and suicidal behaviors has been reported in the media and psychiatric literature. The impetus for this focus was the addition of a black box warning by the U.S. Food and Drug Administration (FDA) on the potential increased risk of suicidal ideation in children, adolescents, and young adults treated with SSRIs. Of note, within the study population from which the original warning was issued, there were no completed suicides. This warning stirred a debate on the risk versus the potential beneficial effects of treatment with this class of medications. Subsequent analysis of the FDA database using a standardized algorithm for assessing suicidal events, termed the Columbia Classification Algorithm of Suicide Assessment (C-CASA), suggests that misclassification of suicidal events may have led to an overestimation of true risk (Posner et al. 2007). Observational studies have shown that treatment, specifically the use of SSRIs, has a protective effect on emergent suicidal behavior (Gibbons et al. 2005, 2007; G. E. Simon and Savarino 2007). Additional research has shown the highest number of suicide attempts in the month before treatment, suggesting that suicidal behavior is often a precipitant for seeking treatment rather than a consequence of antidepressant use (G. E. Simon and Savarino 2007). This particular study compared patients entering psychotherapy to those receiving antidepressant medication, and there was no difference in the rates of suicide-related behaviors in either treatment group, strongly suggesting that suicidality is a reflection of the underlying disease and not of the treatment. One way of solving this conundrum is to use toxicological analysis to determine the presence of antidepressants in suicide

victims. One study of more than 5,000 adult suicides found most had not taken antidepressants immediately prior to death, despite being diagnosed as being depressed (Isacsson et al. 1997). Similar results were found in adolescent populations (Isacsson et al. 2005). With the addition of the black box warning and the subsequent publicity, utilization of antidepressants in the pediatric and adolescent populations has fallen, with a coincident increase in suicide-related behaviors (Nemeroff et al. 2007). In summary, despite claims to the contrary, the evidence suggests that antidepressant medications exert a protective effect on suicide risk.

The relationship between suicidal ideation, attempted suicide, and completed suicide is complex (Moscicki 1997). No direct relation exists between any one of these states and the others. In one population-based study of completed suicides, 56% of the individuals were successful on the first attempt (Isometsa and Lonnqvist 1998). In another comprehensive study of completed suicides, 75% had no contact with mental health providers in the year prior to death (Appleby et al. 1999). One ominous finding in this study was that 16% of the suicides occurred while the victims were inpatients in psychiatric wards, and 24% occurred within 3 months after discharge from psychiatric facilities. In a 10-year follow-up study of patients admitted to the hospital for a medically serious suicide attempt, 25% of the cohort made a second attempt, and 12% eventually died by suicide, with the highest rate of completed suicides occurring in the 2 years following the index admission (Isometsa and Lonnqvist 1998). The expression of suicidal ideation and a history of previous suicide attempts appear to identify a large group of at-risk patients, but only a small percentage of these patients go on to complete suicide. Understanding which patients will go on to complete suicide involves a comprehensive assessment of suicide risk factors.

Suicide risk is estimated by assessing both acute and chronic risk factors (Table 62–2), which include patient characteristics, nature of suicidal behavior, availability of a high-lethality means, and level of and access to psychosocial support systems (e.g., family, friends, community) (R. C. Hall et al. 1999; R. I. Simon and Gutheil 2002). This is an example of a psychiatric emergency in which acquiring reliable and accurate past and collateral history is essential, which may lead to some breach of patient confidentiality. Acute risk factors are most predictive of emergent suicidality and should carry the most weight in the decision to hospitalize a patient (Fawcett et al. 1991).

TABLE 62–2. Acute and chronic risk factors for suicide

Acute	Chronic
Increasing anxiety/frank panic attacks	Gender (male:female = 4:1)
Psychic turmoil	Age (18–24 years; >65 years)
Global insomnia	Chronic illness
Mood-congruent nihilistic delusions	Race (white:nonwhite = 2:1)
Profound hopelessness	Presence of a mental illness
Recent discharge from a psychiatric hospital	Substance abuse/dependence
Substance intoxication	Access to high-lethality means
Access to high-lethality means	Previous suicide attempts
Previous suicide attempts	Family history of suicide

Acute Risk Factors

Acute risk factors are much more predictive of emergent suicidality than chronic risk factors. Acute risk factors include increasing anxiety and frank panic attacks, psychic turmoil, global insomnia, mood-congruent nihilistic delusions, profound hopelessness, and recent discharge from a psychiatric hospital (Busch et al. 2003; Fawcett 1992; Fawcett et al. 1991). Patients who are experiencing the

first three of these symptoms should be viewed as being at particularly high risk regardless of whether they verbalize suicidal ideation. In terms of recent psychiatric hospitalization, the 3-month period following discharge poses a significant period of vulnerability, with one population study indicating 7.8% of the suicide victims completed suicide within 1 month of discharge (Deisenhammer et al. 2007).

Active substance intoxication is another acute risk factor. Recent alcohol consumption plays a role in 25%–50% of all suicides, and the consumption of both alcohol and cocaine may be particularly dangerous (Cornelius et al. 1998). Alcohol intoxication is related to higher rates of completed suicide, while cocaine intoxication is related to higher rates of suicidal ideation (Garlow 2002; Garlow et al. 2003). In this comprehensive series of suicide victims, 40% had alcohol or cocaine detected at the time of autopsy, indicating that the substance was consumed within 48 hours of death (Garlow 2002). Fully 21% of these suicide victims had blood alcohol levels above the legal limit for intoxication (0.08 μg/mL). Cocaine intoxication doubles the risk of suicide in white teenagers compared with African American teenagers (Garlow et al. 2007).

Previous suicide attempts are known precursors for completed suicide; thus, nonlethal suicide attempts are acute risk factors (Deisenhammer et al. 2007; Isometsa and Lonnqvist 1998; Tejedor et al. 1999). The risk for completion is notably higher in the time period following a suicide attempt (Conwell et al. 1996). Consideration should be given to the actual lethality of the attempt; the patient's perception of that lethality; efforts made by the patient to ensure detection or nondetection; calls for help by the patient to medical or law enforcement agencies; contacts to friends or family during the attempt; and use of a firearm. All of these factors illuminate the actual suicidal intent of a patient. A person who took a lethal overdose in a secluded location with no contact to others and who was discovered by accident represents a much higher risk than a person who took a sublethal overdose in a witnessed situation or who immediately called someone to report the overdose or ask for help. Access to firearms must always be determined in a suicide attempt and in someone who appears to be at high risk (Conwell et al. 2002; Miller et al. 2002; Romero and Wintemute 2002).

Other behaviors that should be noted include giving away possessions, placing financial and legal affairs in order, and showing extreme social withdrawal or severing previous interpersonal relationships. Reliable assessment of these behaviors requires collateral history from individuals close to the patient.

Chronic Risk Factors

Chronic risk factors for suicide set the background on which acute risk factors are evaluated. They are derived from population-based analyses of suicides and often are not amenable to any therapeutic intervention, since they are primarily demographic characteristics of people who have died by suicide (Kessler et al. 1999; Moscicki 1997). Males complete suicide four times more often than females do, but females attempt suicide three times more often than males. Males tend to choose more lethal and violent means of suicide than do females. Among males, firearms are the most commonly used (57.6%) method of suicide (National Center for Injury and Prevention and Control 2005). Individuals age 65 years and older constitute 13% of the population but account for 19% of the suicides, making older age a significant chronic risk factor. The suicide rate for white men older than 85 years is 65 deaths per 100,000 population. A coincident risk factor is chronic illness, especially if it was diagnosed in the previous year. Another at-risk group is teenagers and young adults between the ages of 18 and 24 years, in whom suicide is the third leading cause of death.

Whites complete suicide two times more often than nonwhites, with white males accounting for 73% of the suicides in 1998 (National Center for Injury Prevention and Control 2002). The suicide rates for Native Americans are 1.5 times the national average. Suicide rates for specific ethnic groups change with the age and gender of the individual, so blanket statements of risk are not necessarily accurate.

In one study, African American males constituted the largest group, numerically and statistically, of teenage suicide victims but accounted for only 26% of victims from all age groups. In this same data set, African American females accounted for only 3% of all suicides, with only one occurring in an individual older than 45 years (Garlow et al. 2005).

Approximately 90%–95% of suicide victims have a major psychiatric illness, of which approximately half have a mood disorder (Angst et al. 2002; Fawcett 1992; Harris and Barraclough 1997). Male bipolar patients are at higher risk, especially those at an earlier phase of the illness, those who are currently in a depressed state, and those with comorbid substance abuse (Simpson and Jamison 1999). Patients with alcohol and other substance use disorders have higher rates of completed suicide than the national average, with alcoholic patients having a suicide rate twice the national average (Fowler et al. 1986). For alcoholic patients, comorbid depression and recent interpersonal loss increase risk (Murphy and Wetzel 1990; Murphy et al. 1992). A family history of suicide increases suicide risk independent of a family history of mental illness (Qin et al. 2002, 2003).

Patients with personality disorders often express ongoing suicidal ideation; as a result, suicidality becomes embedded in their sense of self (Soloff et al. 1994). This can manifest as repeated acts of parasuicidal or gestural self-injurious behavior, such as cutting and sublethal overdoses. These patients can be very difficult to manage and can put a great deal of strain on the mental health services delivery system. A consistently applied treatment plan, restrained responses on the part of clinicians and staff (minimizing countertransference behaviors), and use of secure 24-hour patient observation areas can be particularly useful in managing these patients. The goal is to allow patients to deescalate and calm down so that they can ultimately be discharged back into their ongoing outpatient treatment regimens (Maltsberger and Buie 1974).

Protective Factors

In formulating a suicide risk assessment, it is important to note protective factors in addition to the presence or absence of acute and chronic risk factors. One study of depressed patients without a history of suicide attempts found that the following served as protective factors: an expression of more responsibility toward family, more fear of social disapproval, more moral objections to suicide, greater coping skills, and greater fear of suicide (Malone et al. 2000). Social connectivity also serves a protective role for depressed patients, as first described by Emile Durkheim (1951). Having close familial relationships, living with another person (family or friend), and having dependent children are all protective factors. Being involved in cultural groups such as organized religion and having moral objections to suicide are associated with lower rates of suicide (Dervic et al. 2004, 2006).

Generating a comprehensive suicide risk assessment involves organizing and balancing risk with protective factors. Clear documentation of these risk/protective factors, steps taken toward intervention, and associated clinical reasoning are essential. A basic statement indicating competency should also be included. In the case of a chronically suicidal patient, clearly documenting this pattern and obtaining a second opinion to corroborate the treatment plan and objectives may be beneficial.

Management of Suicidal Patients

Ensuring safety is the first and most important step in managing a potentially suicidal patient. This can best be accomplished through admission to a secure patient holding area. If no such facility is available, close observation of the patient by a staff member is another option. In this circumstance, moving the patient to a more secure location is the first treatment goal. Patients who are considered to be particularly high risk may require close observation even after they have been admitted to a secure unit. It is important to note that in one study of inpatient suicides on whom information on precaution status was available, 42% were on 15-minute checks or were observed within 15 minutes of the suicide. Furthermore, 9% of this group was on one-to-one observation at the time of suicide (Busch et al. 2003). Staff assigned to monitor patients should be given specific instructions regarding their role

and responsibilities. Furthermore, there should be guidelines for how to manage attempts toward self-injurious behaviors.

Use of extended observation areas can be useful in clarifying the clinical picture while the patient is maintained in safe surroundings. Patients who are intoxicated and expressing suicidal ideation can be allowed to sober up prior to a more definitive assessment. In one psychiatric emergency setting, cocaine use, but not ethanol use, was associated with suicidal ideation, although the mood state was usually transient, resolving in 48–72 hours (Garlow et al. 2003).

The decision to hospitalize a potentially suicidal patient should take into account both acute and chronic risk factors; specific treatment needs of the patient; availability of other treatment options, including partial hospitalization, day treatment, and crisis group home settings; and social support network for the patient. No-harm contracts between patients and clinicians are not useful in making treatment decisions with suicidal patients (Kroll 2000; R. I. Simon 1999). Of psychiatric inpatients who committed suicide, 50% had made such no-harm contracts, and 67% had denied suicidal ideation on the day of the suicide (R. I. Simon 1999). Focusing on the acute behavioral state of the patient (anxiety, agitation, and insomnia), the presence of chronic risk factors, and access to high-lethality means (firearms) is much more relevant to making the decision to hospitalize the patient.

Patients who are not hospitalized require close follow-up, including a detailed treatment plan, an identified treatment provider, and instructions for the patient and family members on what to do in case of symptom worsening. For individuals not hospitalized and for those recently discharged from the hospital, interventions should be made to improve the safety of the patient's living environment. Individuals with access to high-lethality means should be advised to remove these items from the home. Firearms and medications lethal in overdose should be neither in the home nor readily accessible. Family members and friends may be consulted to assist with the removal of these items from the patients' possession (Mann et al. 2005).

Homicidal State

Establishment of a psychiatric diagnosis is the first step in developing a management plan for a patient expressing homicidal ideation. Whereas suicide most often occurs in the context of a mental illness, homicide and homicidal behaviors often do not. There is a relation between sadness and other negative affective states and suicide, but there is no correlation between these mood states and homicidal or violent acts (Apter et al. 1991). Nonetheless, a patient may develop homicidal ideation in the context of a psychotic disorder, particularly disorders that include firmly held paranoid, persecutory, or erotomanic delusions. If such delusional beliefs are driving the expression of homicidal ideation, involuntary hospitalization would be the appropriate course of action.

Expressions of anger, hostility, rage, and violent intent occur in many interpersonal situations and conflicts in which the perpetrator is not afflicted with a psychiatric disorder. In these cases, once a determination has been made that the individual is not psychotic or delusional or expressing homicidal ideation on the basis of some other psychiatric disorder, appropriate interventions are in the domain of law enforcement agencies and not psychiatrists. Such an individual would not benefit from a psychiatric hospitalization but would instead divert scarce resources away from patients who truly would benefit from such an intervention.

If a patient who is expressing homicidal ideation is not admitted to a psychiatric facility, the clinician must give very careful consideration to the need to notify the intended victim and law enforcement agencies based on the principles set forth in *Tarasoff v. Regents of the University of California* (1976; R. I. Simon 1998; Walcott et al. 2001). This case established a precedent for mental health workers to breach confidentiality to notify an intended victim and law enforcement agencies if they are aware of a patient's plan to harm that victim. Clinicians should consider making a *Tarasoff* notification to the intended victim any time a patient who has expressed homicidal ideation is discharged, regardless of

whether that patient has a psychiatric diagnosis. Adoption of the principles set forth in the *Tarasoff* ruling varies by state; therefore, awareness of and adherence to the particular laws within one's own jurisdiction are essential.

Predicting which individuals may act on homicidal ideation is very difficult (Resnick and Scott 2000). Factors that contribute to this assessment are the specificity of the plan, identity of the victim, access to high-lethality means (firearms), capacity of the patient to persist in the plan, and proximity of the perpetrator to the intended victim (Borum and Reddy 2001). Even with a careful history, assessment, and appropriate intervention, preventing an adverse outcome may not be possible. In the *Tarasoff* case, the police determined that the perpetrator was not a threat when they interviewed him, but he eventually carried out the lethal act 3 months later.

Grave Disability and Inability to Care for Self

Another condition for which involuntary commitment laws exist is for patients who by virtue of a mental illness are unable to care for themselves; some states also include "as a result of substance abuse disorders" under this heading (K. T. Hall and Appelbaum 2002). The consideration is whether the patient cannot provide adequately for basic needs, shelter, food, and medical attention because of a mental illness. Common manifestations of this situation include when the patient with a psychotic disorder is living on the streets, without regular or adequate nutrition, and is possibly neglecting ongoing medical conditions. This situation is not the same as that in which a person is homeless because of some other occurrence or circumstance, because homelessness does not in itself constitute grave disability. Another common situation that falls under this heading is when a patient with dementia or other profound cognitive impairments has wandered away from his or her caregivers. In this case, effort should be focused on establishing the identity of the individual and returning him or her to the appropriate facility. If this is a new-onset cognitive impairment, the patient should be hospitalized for definitive evaluation and diagnosis.

Notification of Third Parties

As noted earlier, the principles set forth by the *Tarasoff* ruling in California encourage clinicians to act in the best interests of the intended victim, with notification of the intended victim and law enforcement agencies in the case of expressed homicidal ideation. As in the case of assessment of suicidal and homicidal risk, this may result in a breach of patient confidentiality. This places a unique burden on psychiatrists—to predict future behavior of a patient and to assume responsibility for the welfare of another person with whom the psychiatrist does not have a therapeutic relationship.

Another circumstance that requires breach of patient confidentiality is notification of authorities in cases of suspected child abuse and neglect. All states have statutes that require clinicians of all disciplines to notify the appropriate agency in the case of suspected child abuse. Many states also have laws for reporting elder abuse and abuse of other vulnerable individuals. Specifics of these laws vary with each jurisdiction.

PSYCHIATRIC EMERGENCIES REQUIRING MINIMAL OR ADJUNCTIVE PHARMACOLOGICAL INTERVENTION

Psychiatric emergencies requiring minimal or adjunctive pharmacological intervention occur in many different situations, although many share a common thread of developing in response to some discrete, identifiable stressor (Table 62–3). The practice of crisis intervention psychiatry involves identifying the root cause or stressor of the presenting syndrome and developing a focused treatment plan. The principal therapeutic goals are to alleviate short-term distress, rapidly return the patient to his or her previous level of functioning, and prevent the development of a more serious long-term syndrome. The judicious use of psychopharmacological agents, in concert with psychotherapeutic, psychosocial, and family system interventions, can be particularly effective in these emergencies.

TABLE 62–3. Psychiatric emergencies requiring minimal or adjunctive pharmacological intervention

Emergency	Intervention
Adjustment disorder or acute grief	Diagnostic/psychosocial assessment Psychotherapy Social and family system intervention Short course of sedative-hypnotic Short course of benzodiazepine Selective serotonin reuptake inhibitor
Rape, assault, or trauma	Medical evaluation and treatment Law enforcement Psychotherapy Short course of sedative-hypnotic Short course of benzodiazepine Insult-specific psychotherapy Rape counseling Spousal abuse counseling Violence victim counseling
Borderline personality disorder	Controlled environment/deescalation Structured psychotherapies Low-dose neuroleptics
Panic disorder	Medical evaluation Short course of benzodiazepine Treatment referral

Some conditions in this category require a more thorough diagnostic evaluation and long-term pharmacological management, but in the short term, these agents may or may not be required. Examples of this situation are new-onset panic disorder, dissociative states, catatonia, mania, and conversion disorders. Any of these conditions occurring in a previously well individual, with no history of mental illness, require comprehensive medical evaluation and diagnosis. The long-term management of patients with panic disorder, mania, or psychotic disorders will undoubtedly involve psychopharmacological agents, but these agents may not be required in the immediate setting, depending on the severity of the presenting behavioral syndrome.

Adjustment Disorder

Adjustment disorders are defined as the maladaptive response to an identifiable psychosocial stressor within 3 months of onset of the stressor, with the symptoms having persisted for no more than 6 months (American Psychiatric Association 2000).

The common clinical manifestations of adjustment disorders encountered in psychiatric emergency settings are patients experiencing a mixture of anxiety, depressive, and neurovegetative symptoms in response to some external stressor or crisis. DSM-IV-TR (American Psychiatric Association 2000) nosology provides subtype designations for characterization of the predominant symptoms of the adjustment disorder: with depressed mood, with anxiety, with mixed anxiety and depressed mood, with disturbance of conduct, and with mixed disturbance of emotions and conduct. The potential stressors are myriad, including death of a family member or friend, job loss, diagnosis of a serious medical condition, divorce and other disturbances of family function, financial hardship, and many other circumstances.

The principal interventions for adjustment disorders are psychotherapeutic, educational, and psychosocial. Most crises have a natural time course and resolution. Feelings of distress in response to many of these insults are innate and expected. Psychoeducational interventions are aimed at helping the patient realize that the syndrome is self-limited and expectable in response to the stressor. Often, these patients have a sleep disturbance, so the short-term use of a soporific (diphenhydramine 25–50 mg, hydroxyzine 25 mg, trazodone 50–100 mg, mirtazapine 7.5–15.0 mg), a sedative-hypnotic (zolpidem 5–10 mg, zaleplon 5–10 mg, eszopiclone 2–3 mg, ramelteon 8 mg), or a benzodiazepine (lorazepam 1–2 mg, diazepam 5 mg) could be considered to assist in reestablishing a normal sleep–wake cycle. If daytime anxiety symptoms are particularly severe and debilitating, daytime use of a benzodiazepine may be considered, but this must be done cautiously, because there is no evidence indicating that the early use of such agents prevents the eventual development of more serious disorders such as posttraumatic stress disorder (PTSD) (Gelpin et al. 1996). The goal of any of these interventions is to assist the patient to return to his or her previous functional level as rapidly as possible.

Bereavement falls into this category and can be on the severe end of the spectrum, especially with the loss of a spouse or child. Because many reactions to such losses are culture-bound, a patient's response to a loss must be evaluated against the background of culturally normative behavior. In normal grief reactions, additional therapeutic focus should be on the involvement of family, friends, religious and spiritual figures, and other members of the patient's community.

Bereavement can be distinguished from a major depressive episode on the basis of several criteria. The presence of suicidal ideation, excessive guilt, prominent psychomotor retardation, hallucinations, preoccupation with worthlessness, or symptoms that last for longer than 2 months are not consistent with a diagnosis of uncomplicated bereavement. Further evaluation and more intensive interventions are necessary in these cases.

Acute Trauma

Patients who have been exposed to an acute psychological trauma are at risk for developing acute stress disorder (ASD) or PTSD. The DSM-IV-TR definition of traumatic events includes direct personal experience of an event that involves actual or threatened death, injury, or threat to one's physical integrity or witnessing such an event or learning about such an event happening to a family member or close associate. Most people who experience such traumas do not go on to develop any psychiatric disorder, but a significant minority, up to 30%, will develop PTSD. One theoretical formulation of PTSD is the failure of the normal recovery process after experiencing a trauma (Foa et al. 1989).

Psychological debriefing has become one of the standard interventions after traumatic events (Mitchell 1983). A trained moderator conducts the debriefing with the goal of encouraging the expression of thoughts and feelings about an event shortly after it has occurred. This type of intervention is commonly offered to both the victims of a trauma and the care providers (e.g., police officers, firefighters, emergency medical technicians) that were involved. Evidence shows that the timing of the debriefing is critical and that this might not be the ideal posttraumatic intervention in all situations (Campfield and Hills 2001; Greenberg 2001). An evolving approach to immediate trauma intervention is to assess the risk of a patient developing PTSD and educate the patient about normal reactions to trauma and potential symptoms of PTSD. Theoretical frameworks suggest that adrenergic activation during times of stress contribute to the solidification of memories in the hippocampus. Attempts have been made to test this theory by administering a β-adrenergic antagonist within 6 hours of the traumatic event to assess whether blocking this receptor may lead to a decreased intensity and imprinting of the stored memory. Results of such investigations are promising but warrant the need for further investigation (Pitman et al. 2002; Vaiva et al. 2003).

Treatment referrals should be made to appropriate providers in the event that a patient develops

symptoms of ASD or PTSD over time. Behavioral indicators of risk of developing PTSD include heightened levels of arousal and coping via disengagement after a traumatic event (Mellman et al. 2001). Personalization of the traumatic event, especially thoughts that one might die, is another risk factor. The typical time course for posttraumatic reactions to resolve is on the order of 4 weeks. During this time, it is extremely common for all trauma victims to experience some of the symptoms of PTSD. One of the main early therapeutic goals should be to educate patients about this time course and to encourage them to return to treatment if these symptoms persist past 4 weeks or become particularly debilitating. Referral to trauma-specific psychotherapies (rape crisis, violent crime, survivor groups) can be helpful to victims of these specific insults.

The role of the emergency psychiatrist in the face of a national disaster was assessed following the attacks on the United States on September 11, 2001. In the wake of the terrorist attacks on 9/11, studies have assessed access to mental health care. Some early reports suggested that 44% of Americans reported "substantial symptoms" of psychological distress following the attacks (Schuster et al. 2001). Another study suggests that the residents of the communities that were directly affected by the attacks were significantly distressed by the events, while U.S. communities as a whole did not experience an increase in emergent mental health–related complaints (Catalano et al. 2004). In the wake of a national disaster, the emergency psychiatrist should be prepared to deal with trauma-related symptoms of stress.

Medication recommendations are the same as for adjustment disorders. Two SSRIs, sertraline and paroxetine, have a U.S. Food and Drug Administration (FDA)–approved indication for treatment of PTSD symptoms once the full-blown syndrome has developed. Other SSRIs may share a similar pharmacological profile and subsequent clinical utility. Whether the early use of SSRIs after a trauma prevents the development of PTSD is an open question. One study using animal models suggested that immediate postexposure administration of an SSRI (in this case, sertraline) reduced anxiety-like and avoidant behavior, decreased hyperarousal responses, and diminished the overall incidence of extreme (PTSD-like) behavioral responses, compared with a delayed treatment (7 days posttrauma) regimen and with saline controls (Matar et al. 2006). Other studies have evaluated the use of brief cognitive-behavioral therapy for patients with acute PTSD. One such study indicated accelerated rates of recovery in patients who received this intervention, although it did not influence the long-term outcome (Sijbrandij et al. 2007).

The use of benzodiazepines is controversial in the context of acute trauma. While these medications may be useful in decreasing overall levels of anxiety, there is no clinical evidence supporting their use as prophylaxis against the development of PTSD. The Consensus Statement on PTSD from the International Consensus Group on Depression and Anxiety discouraged the use of benzodiazepines secondary to limited efficacy, concern for tolerance and withdrawal, and the possibility of "impairment of learning" (Ballenger et al. 2000, 2004). In general, these agents should be considered to have a secondary or augmentation role in the treatment of PTSD. If the decision is made to use these medications, long-half-life agents, such as clonazepam and diazepam, minimize the risk of withdrawal or rebound anxiety (Davidson 2004).

If PTSD symptoms persist after 4 weeks or become increasingly debilitating 2–3 weeks after a traumatic event, consideration should be given to use of an SSRI. In addition to SSRIs, recent studies suggest a role for a novel psychotherapeutic treatment, eye movement desensitization and reprocessing (EMDR), in the treatment of adult trauma survivors. In one study, 75.0% of adult-onset versus 33.3% of child-onset PTSD subjects receiving EMDR achieved asymptomatic end-state functioning, compared with none in the SSRI group (van der Kolk et al. 2007).

Conditions That Require Medical Evaluation

With any acute change in mental status or sudden-onset change in behavior in a previously well

individual, organic causes must be considered first, before it is assumed that the symptoms are a manifestation of a previously undiagnosed psychiatric disorder (Frame and Kercher 1991; R. C. Hall et al. 1978, 1981). This is especially true when the syndrome occurs outside of the usual age-based window of vulnerability. For example, new-onset psychotic symptoms in a patient older than 40 years or mania in a patient older than 50 years should be considered to be due to a medical condition until proven otherwise. Other psychiatric disorders do not have as clearly defined windows of vulnerability as schizophrenia and bipolar disorder, but should on initial presentation be suspected as due to a medical condition.

Panic Disorder

A patient presenting for the very first time with dyspnea, tachycardia, diaphoresis, chest pain, and light-headedness should receive a thorough medical evaluation before being assigned a diagnosis of panic disorder. Many different conditions can present with some or all of these symptoms, including unstable angina and myocardial infarction, hypoglycemia, anemia, pulmonary embolism, asthma, obstructive pulmonary disease, gastroesophageal reflux disease, irritable bowel disease, hyperparathyroidism, hyperthyroidism, pheochromocytoma, Huntington's disease, Parkinson's disease, seizure disorder, and autoimmune disorders, such as systemic lupus erythematosus (Roy-Byrne et al. 2006). Only after these medical conditions have been ruled out should a diagnosis of panic disorder be entertained. During the initial attack, use of a benzodiazepine may be helpful to make the patient more comfortable, but care should be taken not to mask symptoms of a more serious underlying condition. Current FDA-approved medications for panic disorder include alprazolam (a benzodiazepine), sertraline and paroxetine (SSRIs), and venlafaxine (serotonin–norepinephrine reuptake inhibitor). SSRIs tend to be utilized first line because of their general tolerability, lack of potential for dependence/misuse, and safety profile (Katon 2006). Currently, the gold standard of clinical practice in the definitive long-term management of panic disorder is the use of SSRIs in concert with cognitive-behavioral therapy.

Dissociative Episodes

Amnestic and acute confusional states should always be considered to be due to a medical or neurological condition until proven otherwise. Amnestic symptoms are common after head injury, during cerebrovascular accidents and transient ischemic accidents, in postictal states, with brain tumors, in intentional and unintentional intoxications, and in many other medical conditions. Another important diagnostic consideration is of a delirium, which could have any number of medical or metabolic causes. Establishing the correct diagnosis in this type of patient is facilitated by extended observation, with repeated assessments. This allows for detection of the fluctuating levels of consciousness and awareness common in delirium and of the temporal evolution of the amnestic symptoms. Unobtrusive observation of these patients also allows for assessment of purposeful, deliberate, and organized behaviors, which usually are observed in patients with psychogenic or factitious amnestic conditions but often are not seen in those with an organic condition.

Catatonia

Catatonia is a syndrome of motor dysregulation characterized by the presence of at least two of the following symptoms for more than 24 hours: mutism, immobility, negativism, posturing, staring, rigidity, stereotypy, mannerisms, echophenomena, perseveration, and automatic obedience (Fink and Taylor 2006; Taylor and Fink 2003). Catatonia can be diagnosed in 7%–15% of psychiatric patients in acute inpatient services and emergency room settings (Fink and Taylor 2006). Although commonly classified as a psychotic spectrum disorder, catatonia is more frequently associated with mania, melancholia, and psychotic depression than it is with schizophrenia. If a patient has not had documented previous episodes of catatonia in conjunction with one of these psychiatric disorders, a medical cause should be sought vigorously. Episodes of catatonic behavior can occur in a variety of

neurological and medical conditions, including metabolic encephalopathies, viral encephalitis, cerebrovascular accidents, epileptic episodes, hypercalcemia, and adverse medication (neuroleptic) and drug (phencyclidine [PCP]) side effects. These conditions should be ruled out before a psychiatric diagnosis is made. Although no established standard of care exists for the treatment of catatonia, acceptable treatment options include high-dose intravenous barbiturates (e.g., amobarbital) and benzodiazepines (e.g., lorazepam), as well as electroconvulsive therapy (ECT) (Fink 2001; Rosebush et al. 1990). However, definitive treatment is based on the underlying diagnosis.

Mania and Psychosis

New-onset mania and psychosis should always be approached as potentially due to a medical condition. The clinical context will guide the urgency of the medical evaluation. New-onset psychotic symptoms in a 40-year-old and new-onset mania in a 50-year-old should prompt an urgent medical evaluation. Such symptoms appearing in an adolescent or a young adult should still be evaluated medically, although not with the same urgency as in the older adult. These symptoms can be caused by brain tumors, cerebrovascular accidents, autoimmune disorders, multiple sclerosis, and hyperthyroidism. Many medications, including exogenously administered steroids and stimulants, as well as illicit drugs can provoke manic and psychotic symptoms. Therefore, a thorough physical examination and a urine drug screen are essential components of the diagnostic workup.

Conversion Disorder

Conversion disorder is a diagnosis of exclusion. Accordingly, new-onset neurological symptoms, including nonepileptic seizures, nonanatomical movement disorders, paresthesias, paresis, and amnestic syndromes, should be thoroughly evaluated before being attributed to a psychogenic cause. Management of conversion symptoms includes a complete medical assessment and reassurance that the symptoms will resolve with time. In one case report describing treatment of a patient with acute conversion disorder, use of intravenous lorazepam in combination with hypnosis led to a full recovery (Stevens 1990). Long-term management involves both physical rehabilitation and treatment of the underlying psychological conflict or distress. Family therapy can be a useful tool, given that family dynamics are often an essential part of the psychosomatic response to stress (Hurwitz 2004). Similar treatment strategies can be used for the treatment of somatization disorder.

PSYCHIATRIC EMERGENCIES THAT USUALLY REQUIRE PHARMACOLOGICAL INTERVENTION

Management of severe behavioral emergencies usually requires psychopharmacological intervention prior to definitive diagnosis (Table 62–4). Many psychiatric patients will have episodes of disorganized, disinhibited, agitated, aggressive, or violent behavior. These behavioral states can occur in patients who are psychotic, manic, or intoxicated as well as in those who have organic syndromes such as dementia or delirium. Patients who are experiencing severe medication side effects or adverse events also require pharmacological intervention, as do patients with substance use disorders in withdrawal states.

TABLE 62–4. Psychiatric emergencies that *usually* require pharmacological intervention

Emergency	Intervention
Assaultive, aggressive, or violent behavior	Calm, controlled staff Adequate staff/"show of force" Seclusion/stimulus minimization Physical restraint
Primary psychotic or mood disorder	Medication: Lorazepam

Emergency	Intervention
	Haloperidol
	Atypical antipsychotics
	Definitive diagnosis and treatment plan
Delirium	Diagnose delirium vs. other disorder Definitive medical diagnosis Treat underlying cause Intravenous (iv) or intramuscular (im) haloperidol
Ethanol or sedative-hypnotic withdrawal	Benzodiazepine to stabilize withdrawal symptoms Controlled taper under supervision Refer to chemical dependency treatment
Alcohol withdrawal delirium	Medical intensive care Supportive measures Benzodiazepine taper
Medication side effects	
Neuroleptic-induced dystonia	Acute: Diphenhydramine 25–50 mg iv Maintenance: Diphenhydramine 25–100 mg qd, or Benztropine 0.5–4.0 mg qd, or Trihexyphenidyl 2–10 mg qd
Neuroleptic-induced akathisia	Lower antipsychotic dose Propranolol 10 mg two to three times daily Benzodiazepine
Neuroleptic malignant syndrome	Discontinue offending agent Medical intensive care/support: Cooling Hydration Anticoagulation Medical intensive care/support: Cooling Hydration Anticoagulation Dantrolene Benzodiazepine Electroconvulsive therapy

Emergency	Intervention
Anticholinergic delirium	Discontinue offending agent(s) Supportive measures
Hypertensive crisis	Management of blood pressure Supportive measures
Serotonin syndrome	Discontinue offending agent Medical supportive measures/intensive care Benzodiazepine
Priapism	Discontinue offending agent Medical supportive measures Urology evaluation if condition does not resolve
Selective serotonin reuptake inhibitor discontinuation syndrome	Reassurance; restart medications

Assaultive, Aggressive, or Violent Behavior

Assaultive, aggressive, and violent behaviors can have many different etiologies, including psychotic or delusional ideation secondary to a primary psychotic or mood disorder, substance intoxication, acute confusional states associated with dementia and delirium, rage attacks in patients with personality disorders, and deliberate, volitional acts by antisocial individuals. The most important chronic risk factor for predicting violent behavior is a history of such behavior. Acute risk factors include over- or undercontrolled behavior. The former refers to a patient with decreased psychomotor activity, tension, anger, and paranoia, whereas the latter refers to a patient who is agitated, intrusive, and verbally provocative. Intoxication is an independent acute risk factor that can potentiate violent behaviors in patients with many different diagnoses.

The initial diagnostic effort should be to globally assess the behavioral state causing the aggressive behaviors, because this will affect subsequent treatment decisions. Concurrently, the focus should be to maintain a safe environment for the patient, other patients, and the staff. A well-trained staff of an adequate number in an appropriately designed facility is the best preventive strategy for minimizing violent episodes. Staff members who are trained to respond in a calm, deliberate, and nonthreatening manner help to establish an atmosphere of order and control. Preventing a violent act from occurring is preferable to responding to a violent act after it has occurred; thus, ongoing assessment of patients is essential, as is the proactive use of sedating medications. It is better to have a patient take a medication voluntarily and orally before his or her behavior has escalated than to be required to involuntarily medicate the patient after a crisis has occurred. This cooperation of care is the first step in establishing a therapeutic alliance, which in turn can further mitigate the risk of escalation.

There are several options in the acute management of the agitated patient. Orally available agents include several benzodiazepines and atypical antipsychotics. Lorazepam in 2-mg doses given every 45–60 minutes usually will sedate most patients by the second dose. Other alternatives are 15–20 mg of olanzapine, 4–6 mg of risperidone, or 5 mg of haloperidol in a single oral dose. The decision of which agent to use is based on the underlying diagnosis. If a patient with a known diagnosis of schizophrenia or bipolar disorder appears to be experiencing a psychotic or manic decompensation, then an atypical antipsychotic should be used. If the diagnosis is not known or is unclear, then lorazepam is a better choice. This is especially true given that acute intoxication with some agents—for example, anticholinergics like diphenhydramine—may be worsened by the addition of atypical antipsychotics. Lorazepam is also most appropriate for patients who are violent as a result of intoxication with drugs or alcohol.

The administration of oral medications is preferred over the use of parenteral medications when the agitated patient is willing to accept such an intervention. Research has suggested that clinicians may overutilize intramuscular injections out of ease of treatment. One study in a Geneva, Switzerland, psychiatric emergency service evaluated the rates of involuntary injections in patients being observed for psychomotor agitation. The results supported the theory of overutilization, as there was a 27% reduction in involuntary injections during a 3-month observation of treatment (Damsa et al. 2006). Given these findings, efforts should be made to encourage voluntary administration of medications if possible.

New alternatives to the established pill or tablet formulation of second-generation antipsychotics exist and demonstrate positive results in comparative trials. Risperidone M-Tab, Zyprexa Zydis, and Abilify disc melt are currently available rapidly dissolving forms of their parent agents. Risperidone is also available in an oral concentrate solution. These formulations exhibit benefit over the traditional pill formulation in patients who may "cheek," or store the administered medication in their cheek, and dispose of it prior to consumption (Allen et al. 2001, 2005). These formulations display similar pharmacokinetics compared with the traditional pill formulation.

When staff attempts to redirect an actively or imminently violent patient fail, quick and decisive action must be taken. The most direct means to ensure safety of the patient and all others in the immediate area is seclusion and restraint. Adequate numbers of well-trained staff are required to accomplish this rapidly and with minimal chance of injury to the patient and staff. Staff should be trained to manage the situation assertively while maintaining professionalism—that is, not acting in a manner that is punitive or reactive to the patient's behavior. Patients who are restrained also should receive medication, usually via the intramuscular or intravenous route. However, because establishment of intravenous access in a combative patient is often very difficult and is potentially dangerous to the patient and staff, intramuscular is usually the preferred route.

Involuntary administration of psychotropic medications is allowed in emergencies that are considered life-threatening, although rather wide variation exists in the legal definition of life-threatening emergencies and in the practice of administering involuntary medication. Clinicians should be well informed on the local definitions and regulations regarding involuntary administration of psychotropic medication. Accurate and timely documentation of the need for restraint and involuntary medication administration is essential.

Currently, six medications are suitable for intravenous or intramuscular administration in behavioral emergencies. These are lorazepam, diazepam, haloperidol, and injectable preparations of three atypical antipsychotics—olanzapine, ziprasidone, and aripiprazole. Lorazepam is the most useful and should be the mainstay for controlling behavioral emergencies (Battaglia et al. 1997; Foster et al. 1997; Salzman et al. 1991). Lorazepam is rapidly absorbed from intramuscular injections, has a rapid onset of action, has a short half-life, and is anxiolytic as well as sedating. Patients who are being combative generally are experiencing high levels of fear or anxiety, so the anxiolytic properties of lorazepam are an additional advantage. Intramuscular diazepam can be absorbed erratically and thus is not particularly useful. Haloperidol should be reserved for patients who are clearly psychotic, with the expectation that they will receive long-term treatment with an antipsychotic agent.

A sufficiently large dose should be given with the first injection in a behavioral emergency to ensure rapid onset of sedation and to minimize the need for a second or third injection. Lorazepam should be administered in 2-mg doses that can be repeated at 45 minutes if the initial dose is not sufficient. Very rarely will any additional injections be required after a second 2-mg dose of lorazepam. The initial haloperidol injection should be 2.5–5.0 mg and should not be repeated for at least 2 hours. Sufficient time must be given for the medication to be absorbed and for maximal sedation to occur. Under no circumstances should a patient receive more than 5 mg of haloperidol in a single injection or more than two injections (10 mg) in 24 hours, which can provoke a severe dystonic reaction. To prevent

dystonia, 1 mg of benztropine should be included with intramuscular haloperidol. Alternatively, 25 mg of diphenhydramine may be added to prevent dystonia while providing additional sedation via its antihistaminergic mechanism of action. The combination of lorazepam and haloperidol in a ratio of 2 mg of lorazepam to 5 mg of haloperidol is often used to provide adequate sedation and anxiolysis while treating the underlying psychosis. However, unless the patient is obviously psychotic and the plan is for long-term antipsychotic treatment, this combination should be avoided. On the other hand, benztropine is not needed if lorazepam has been given with haloperidol.

The injectable atypical antipsychotics should be reserved for patients who will be given an oral atypical agent after the immediate emergency has resolved. Intramuscular ziprasidone was approved in 2002, and it has been studied in patients with schizophrenia who were psychotic and agitated and is currently indicated for the treatment of these conditions (Daniel et al. 2001; Lesem et al. 2001). In these clinical trials, patients received an initial injection of 10 mg, followed by injections of 5–20 mg every 4–6 hours, for a maximum dose of 80 mg in 24 hours. At the end of 3 days of intramuscular treatment, these patients were converted to the oral preparation of ziprasidone. The intramuscular ziprasidone package insert (Geodon 2008) recommends doses of 10–20 mg, with 10-mg doses repeatable at 2-hour intervals and 20-mg doses at 4-hour intervals. The maximum recommended intramuscular dose in 24 hours is 40 mg. Studies of intramuscular ziprasidone in the treatment of acute agitation note overall efficacy in reducing agitation while relieving anxiety. Intramuscular ziprasidone appears to have a low incidence of extrapyramidal side effects compared with intramuscular haloperidol (Brook et al. 2000). Results from one naturalistic study suggest that the use of intramuscular ziprasidone may reduce time in restraints for agitated patients compared with treatment with a conventional agent (Preval et al. 2005). One drawback of the intramuscular ziprasidone preparation is that it has to be reconstituted with sterile water immediately prior to administration.

Injectable olanzapine has been studied for use in agitated patients with schizophrenia, bipolar mania, and dementia (Breier et al. 2002; Meehan et al. 2001, 2002; Wright et al. 2001). In the schizophrenia trials, patients received up to three individual injections of 2.5–10.0 mg in 24 hours, with the higher doses producing more significant and sustained reduction of agitation. In the bipolar trials, patients received up to three injections of 5 or 10 mg of olanzapine in 24 hours, with significant reduction in agitated behaviors. In the dementia trial, agitated patients received up to three olanzapine injections of 2.5 or 5 mg in 24 hours, with significant reduction in agitation. A recent review of the literature by Tulloch and Zed (2004) concluded that injectable olanzapine was superior to placebo in all study populations and to intramuscular lorazepam in patients with bipolar affective disorder. However, this review further concluded that injectable olanzapine did not differ significantly from intramuscular haloperidol or lorazepam in the management of agitation associated with schizophrenia/schizoaffective disorder or dementia. It is relevant to note that olanzapine is FDA approved for the treatment of schizophrenia and bipolar mania, but not agitation associated with dementia.

Injectable aripiprazole was FDA approved for the treatment of agitation in patients with schizophrenia and bipolar mania in 2006. With a unique mechanism of action as a dopamine partial agonist, aripiprazole presents a new treatment approach in the management of acute agitation. Efficacy studies demonstrate injectable aripiprazole at a dose of 9.75 mg is superior to placebo and comparable to injectable olanzapine. Injectable aripiprazole demonstrated tolerability and symptom reduction without oversedation (Trans-Johnson et al. 2007). One benefit of this formulation is that it is packaged in a 9.75 mg/1.3 mL ready-to-use single vial.

Schizophrenia

Atypical antipsychotics represent the current standard of care for the treatment of acute agitation in patients with schizophrenia (American Psychiatric Association 2004). With proven efficacy in

comparison with haloperidol and improved tolerability, these agents represent the first-line treatment in the agitated psychotic patient (Aleman and Kahn 2001; Currier and Trenton 2002; Yildiz et al. 2003). The only patients in whom this is not the case are those who have been stable long term (5 or more years) while taking a typical antipsychotic. The optimal intervention in a patient with schizophrenia who is experiencing an acute exacerbation is to rapidly initiate treatment with an atypical antipsychotic. In this regard, risperidone and olanzapine are the most useful agents, because both can be initiated at a high therapeutic dose (15–20 mg for olanzapine; 4–6 mg for risperidone) and can be given in multiple oral doses (two or three doses) over a period of 24 hours. Both of these medications, as well as aripiprazole, are available in an orally disintegrating formulation if compliance is in question. However, if compliance is a concern, then one must assess the utility of oral medications in general, and consider an intramuscular medication.

In a patient who is too disorganized or combative to take medication orally, intramuscular administration is the only viable route. Currently, haloperidol, ziprasidone, olanzapine, and aripiprazole are available as injectable preparations. In a patient who is psychotic and agitated, the coadministration of a benzodiazepine during the first few days of treatment can be particularly effective in controlling behavior while the antipsychotic response develops. Studies suggest that this combination may reduce the total antipsychotic dose and potentially result in fewer adverse antipsychotic effects (Salzman et al. 1991; Yildiz et al. 2003). One caveat to this choice of treatment is the recent attention surrounding an increased risk of sedation and cardiorespiratory depression in patients treated with intramuscular olanzapine and intramuscular lorazepam, leading to a warning in the prescribing information provided by Eli Lilly, the manufacturer of olanzapine (Zyprexa 2005).

Bipolar Disorder

Although behavioral emergencies can occur during both manic and depressive mood states, they tend to occur more often during mania. The goal of managing these patients is the establishment of a long-term definitive treatment regimen, which means initiating treatment with a mood-stabilizing agent such as lithium (10–20 mg/kg) or valproic acid (20–30 mg/kg) as soon as possible. Prior to initiating either of these two agents, a serum pregnancy test should be obtained and documented as negative, since both agents are teratogenic. Patients should be monitored for signs and symptoms of adverse side effects and toxicity. Both lithium and valproic acid require time to reach a therapeutic blood level and may take up to 14 days to become fully effective. Until steady state is established, behavioral control can be achieved with oral or intramuscular lorazepam or another benzodiazepine on an as-needed basis or with an atypical antipsychotic such as olanzapine, risperidone, ziprasidone, quetiapine, or aripiprazole, all of which are FDA approved for the treatment of acute bipolar mania. Olanzapine, risperidone, and quetiapine have the advantage of being sedating, which can be useful in an emergency room–type setting. In fact, atypical agents may be preferable to benzodiazepines in the management of acute bipolar mania according to recent studies. A recent review of the literature indicated that intramuscular olanzapine was superior to lorazepam monotherapy in the treatment of agitated manic patients (Tulloch and Zed 2004). Focusing on the long-term treatment goals is of the essence. If the long-term plans do not include an antipsychotic, then lorazepam or another benzodiazepine should be used for short-term behavioral control. If, however, it is known that the patient will require both a mood stabilizer and an antipsychotic for long-term management, then the antipsychotic should be substituted for the benzodiazepine.

Another treatment option in both manic and depressed bipolar patients is ECT. With a rapid onset of action and known efficacy, especially in terms of short-term stabilization, this is a viable treatment option. This could be considered a treatment of choice in patients who are pregnant. Unfortunately, many facilities are not equipped to provide this treatment, and there are legal issues around obtaining informed consent to administer ECT emergently.

Substance Intoxication

Violent and combative behavior by intoxicated patients is a very common occurrence in psychiatric and medical emergency departments. Alcohol, cocaine, and PCP are the main culprits, but methamphetamines, γ-hydroxybutyrate, and hallucinogens also can lead to violent behavior.

Ethanol intoxication is a very common cause of violent behavior in many settings. The appropriate interventions are physical restraint and sedation with a benzodiazepine, in conjunction with haloperidol if the agitation is significant, to allow the patient to become sober while serving as a seizure prophylaxis. Once a patient's blood alcohol level is below the legal limit for intoxication, a more definitive evaluation can be carried out, focusing on presence of an underlying psychiatric diagnosis or other treatment needs. Follow-up options include referral to substance abuse treatment, involuntary commitment if allowed in that jurisdiction, admission to a dual-diagnosis unit or program, or discharge.

Prolonged cocaine use can lead to development of both mood and psychotic syndromes. Transient paranoid states are very common in cocaine users, as are frank delusions and hallucinations. Agitated, paranoid states accompanying cocaine intoxication can lead to significant violent behavior. Interventions are as described previously, including seclusion and restraint, use of intramuscular lorazepam, and possibly use of an antipsychotic if the patient is frankly psychotic. When the patient is no longer intoxicated, the presence of underlying psychopathology can be assessed. Disposition is as described for alcohol: admission to a dual-diagnosis program if the patient has another psychiatric disorder, referral to chemical dependency treatment, or discharge.

PCP intoxication can be particularly provocative of agitated, combative, and violent behavior. Fortunately (or unfortunately), PCP use tends to occur in localized geographical regions and not in others. In areas where PCP use is common, intoxicated persons are common in emergency facilities. PCP intoxication can present with frank psychotic symptoms, agitation, disorientation, and disorganized behavior. Violent outbursts can be sudden, unprovoked, and unexpected. Patients in the throes of PCP intoxication can be very insensitive to pain, so they are prone to continue to fight even if seriously injured. Adequate numbers of well-trained staff are essential when dealing with patients who have been using PCP. The expectation should be that these patients will require seclusion and restraint. Restraint rooms should be dark and quiet so as to minimize stimulation. Intramuscular lorazepam should be used to sedate the patient, and he or she should be allowed to become fully sober before definitive assessment. The half-life of PCP is 20 hours, so these behavioral states can persist for several days before fully resolving.

Methamphetamine, hallucinogens, γ-hydroxybutyrate, and cannabis can cause agitated, disorganized, and even violent behavior. Methamphetamine in particular can have behavioral consequences very similar to those of cocaine. Because of the long half-life of methamphetamine compared with cocaine, this drug can be particularly provocative of frank paranoid and psychotic symptoms. Like PCP use, methamphetamine use tends to be limited to certain geographical regions and not others.

From 1991 to 1994, methamphetamine-related emergency cases tripled nationwide, making it a growing clinical phenomenon (Centers for Disease Control and Prevention 1995). Presenting symptoms often include agitation, hallucinations, suicidal ideation, and chest pain (Derlet et al. 1989). Distinguishing stimulant intoxication from other clinical diagnoses can be challenging given the symptom overlap. Generally, stimulant-induced psychosis tends to be distinguishable from primary psychotic disorders by the absence of a thought disorder and a prominence of visual hallucinations (Harris and Batki 2000). However, given the potential for comorbidity, a positive drug screen does not completely discount the diagnosis of a mood or psychotic disorder. Treatment should focus on maintaining the patient's safety while awaiting the drug's metabolism and dissipation from the patient's system. A more complete diagnostic workup can be completed once the patient is no longer intoxicated.

Delirium

Patients with delirium can become disorganized, agitated, and combative. Delirium is defined as a state of a disturbed level of consciousness with a change in cognition or with perceptual disturbances, during which the symptoms occurs rapidly and tend to fluctuate with time. Delirium may be due to a general medical condition, substance intoxication or withdrawal, or secondary to multiple etiologies (American Psychiatric Association 2000). Delirium is a medical emergency and carries a very high burden of morbidity and mortality. The definitive treatment of delirium requires diagnosing the underlying cause and taking corrective action toward that particular pathology. Interventions aimed at controlling behavior include soft or leather restraints, environmental modification including frequent reorientation of the patient, and use of intravenous haloperidol. Behavioral control is essential so that the patient does not further injure him- or herself or interfere with treatment and to protect staff and other patients. The first intravenous dose of haloperidol should be 2.5 mg. If the patient is still agitated after 2 hours, the dose should be increased to 5 mg. This dose can be repeated in another 2 hours if the patient continues to be agitated. Once the patient is stabilized, a routine neuroleptic regimen should be initiated, dividing the total dose into two or four regular doses. The neuroleptic can be decreased and discontinued as the delirium clears. Benzodiazepines are generally contraindicated in cases of delirium, because they can exacerbate behavioral dysregulation and potentiate the altered level of consciousness.

Dementia

Patients with dementia can become agitated, combative, or psychotic for many different reasons. The most common cause for this is a delirium overlying the dementia. Delirium in these patients can be caused by side effects from medications; infectious processes, which can appear quite minimal or clinically insignificant; and metabolic disturbances from many medical causes. Definitive diagnosis and treatment of the underlying disorder are essential to achieving adequate long-term resolution. Patients with dementia who are not delirious can become agitated as a result of confusion or psychosis inherent in the dementing pathology. In these cases, the best interventions are nonpharmacological, including environmental modification, behavior modification, and supportive measures. Aggressive behavior in patients with dementia can be treated pharmacologically, in the short term with lorazepam or low-dose neuroleptics and in the long term with low-dose neuroleptics, the anticonvulsants carbamazepine or valproic acid, propranolol, serotonin reuptake inhibitors, or buspirone. As is the case in all geriatric medicine, low doses and slow titration schedules are the appropriate course. Recent data suggest an increased mortality risk associated with the administration of neuroleptics in the management of dementia-related psychosis (Schneider et al. 2005). It is important to note that second-generation antipsychotics are not approved for the treatment of dementia-related psychosis and that a black box warning has been placed on the prescribing information of these agents in this population regarding an increase risk of cerebrovascular events and adverse events that are infectious in nature.

Substance Withdrawal States

Alcohol and Sedative-Hypnotics

Alcohol and sedative-hypnotic withdrawal can result in a frank delirium that is life-threatening (Marco and Kelen 1990; Olmedo and Hoffman 2000). The acute signs of early alcohol, sedative-hypnotic, and benzodiazepine withdrawal are similar and include autonomic instability, tremulousness, diaphoresis, and gastrointestinal disturbances. Autonomic signs include tachycardia, hypertension, and hyperthermia. Treatment of this withdrawal state is best accomplished with a long-half-life benzodiazepine. Use of long-half-life agents such as diazepam or chlordiazepoxide prevents peaks and troughs in blood levels, thereby leading to a smoother taper. During the first 24 hours, vital signs should be taken at 2- to 4-hour intervals and additional benzodiazepine given if vital signs are still

elevated. After 24 hours, the total dose should be added up and given as four divided doses, which are then decreased 10%–20% per day. In patients with significant liver disease, lorazepam or oxazepam should be used in preference to other benzodiazepines because their metabolism is not as dependent on hepatic function. It is important to consider concomitant medications, since β-blockers prescribed for a general medical condition may mask the autonomic signs of withdrawal.

Alcohol withdrawal delirium (delirium tremens) is a life-threatening medical condition (Erwin et al. 1998). This syndrome has a very high mortality rate—up to 35% of untreated patients and as high as 5%–15% in optimally treated patients. The delirium usually develops 48–72 hours after discontinuation of alcohol or sedative-hypnotics, peaks around day 4, and can persist for 2 weeks. The symptoms include autonomic instability, fever, disorientation, perceptual disturbances and hallucinations, agitation, and confusion. Patients with delirium tremens should be treated in a medical intensive care unit. These patients typically require physical restraint and vigorous supportive measures. Intravenous haloperidol can be used to control agitation and psychosis, but by the time a patient develops delirium tremens, benzodiazepines are not particularly useful.

Wernicke-Korsakoff syndrome is another consequence of long-term alcohol use. Wernicke encephalopathy is the symptom complex of ophthalmoplegia, ataxia, and an acute confusional state. Wernicke-Korsakoff syndrome is diagnosed if persistent learning and memory deficits are additionally present. Alcoholic patients should receive three daily 100-mg doses of thiamine via the intramuscular route from the day of presentation, followed by three daily oral doses to prevent development of this syndrome. Patients should receive the first intramuscular dose before oral or intravenous administration of a carbohydrate load in order to prevent rapid thiamine depletion and emergent development of Wernicke-Korsakoff syndrome. Patients should also be given folic acid and magnesium replacement supplementation, because nutritional deficiencies are common in alcohol-dependent patients.

Another potentially emergent situation is a patient presenting with an alcohol–disulfiram reaction. Disulfiram (Antabuse) blocks alcohol dehydrogenase, leading to a buildup of acetaldehyde. Subsequent consumption of alcohol produces unpleasant symptoms, including headache, flushing, nausea, and vomiting, creating an aversive reaction to alcohol consumption. No treatment for these mild symptoms is necessary. Serious symptoms such as arrhythmias and respiratory depression can occur and should be treated immediately with supportive measures.

Opiates

Opiate withdrawal can be exceedingly uncomfortable for the patient but, unlike alcohol and sedative-hypnotic withdrawal, is generally not life-threatening. Accordingly, the goal of opiate withdrawal treatment is relief of pain and suffering. Symptoms of opiate withdrawal include dysphoria, anxiety, irritability, craving, mydriasis, piloerection, diaphoresis, nausea, vomiting, diarrhea, rhinorrhea, lacrimation, insomnia, fever, and hypertension. Onset of this syndrome depends on the half-life of the drug used and with heroin is usually 6–8 hours after the last use. The syndrome can last 2–5 days, depending on the individual patient. Most of the symptoms are attributable to upregulation of α_2-adrenergic receptors; as a result, α_2 agonists such as clonidine are very useful. Clonidine in doses of 0.1–0.3 mg every 3 hours, up to 0.8 mg/day, can be given to suppress signs of opiate withdrawal (Ahmadi-Abhari et al. 2001; Akhondzadeh et al. 2000; Charney et al. 1981; Gossop 1988). A major side effect of this regimen is hypotension, so the regimen must be carried out in a medically supervised setting. Clonidine should be avoided in patients who are dependent on both opiates and alcohol or a sedative-hypnotic; clonidine may mask the autonomic signs of ethanol withdrawal without actually preventing the emergence of delirium tremens.

Another approach to opiate withdrawal is to substitute a long-half-life agent such as methadone at a dose of 30–80 mg and then taper off this agent at a rate of 10%–20% per day. This is best

accomplished in a "cocktail" that keeps the patient "blind" to the daily dose. This type of detoxification regimen is recommended in patients who are dually addicted to opiates and ethanol or sedative-hypnotics. A long-half-life opiate and long-half-life benzodiazepine are used to detoxify both dependencies.

Psychotropic Medication Side Effects

Antipsychotics

Several adverse events can occur in patients taking typical antipsychotics and to a lesser degree in patients taking atypical antipsychotics. Dystonic reactions are characterized by extreme muscle contraction and rigidity in a patient with stable vital signs and a clear sensorium. These occur most frequently with high-potency, first-generation antipsychotics (Moleman et al. 1982; Schillevoort et al. 2001). Young males are particularly susceptible to dystonic reactions. Most dystonic reactions are extremely uncomfortable and frightening to the patient. Treatment of these reactions is typically 1–2 mg of benztropine via the oral or intramuscular route. An alternative is diphenhydramine in doses of 25–50 mg via the oral or intramuscular route. Dystonias that include the eyes, the so-called oculogyric crises, are particularly frightening, as are dystonias that cause laryngeal spasms, which can compromise the airway. These reactions should be treated with 50 mg of intravenous diphenhydramine, which provides rapid relief. Maintenance treatment of 1–2 mg of benztropine twice a day or 25–50 mg of diphenhydramine twice a day should be initiated after the acute reaction has resolved (Keepers et al. 1983).

Akathisia is a syndrome characterized by internal restlessness, often perceived as the need to be in motion. This leads to increased psychomotor activity, including pacing, rocking, leg tapping and bouncing, and moving frequently between sitting and standing. The patient may complain of feeling anxious, irritable, or that his or her "skin is crawling." Treatment providers may interpret the anxiety, irritability, and increased motor activity common to patients with akathisia as worsening of psychotic symptoms, resulting in increased administration of antipsychotics. This further provokes the akathisia and consequently worsens the behavioral state. Lowering the dose of the antipsychotic or switching to an atypical antipsychotic are treatment options; the atypical drugs cause akathisia at lower rates compared with typical agents. Propranolol in doses of 10 mg two or three times a day is an effective treatment for akathisia.

Neuroleptic malignant syndrome (NMS) is a potentially fatal delirium that develops in some patients in response to antipsychotic agents (Susman 2001). The diagnosis is made on the triad of symptoms of altered level of consciousness, muscular rigidity (often described as lead-pipe rigidity), and autonomic instability. The autonomic instability includes hyperthermia, tachycardia, labile blood pressure, diaphoresis, incontinence, and occasional dysphagia and bowel obstruction. Associated findings include elevated creatine phosphokinase (CPK), elevated white blood cell count, and metabolic acidosis. Later complications include rhabdomyolysis and renal failure. The main interventions in NMS are discontinuation of the offending agent and provision of general supportive measures, including cooling, rehydration, intensive nursing care, and anticoagulation. A few drugs have been used to treat NMS, including benzodiazepines, bromocriptine (15 mg/day), dantrolene (100–300 mg/day), and amantadine (200 mg/day). ECT also has been used to treat NMS.

The atypical antipsychotic clozapine can cause catastrophic agranulocytosis in up to 1% of patients treated. This usually occurs within 6 weeks to 6 months of initiating therapy with clozapine. As a result, a surveillance program has been put in place so that all patients taking clozapine have weekly blood counts for the first 6 months of therapy, then every other week for 6 months, followed by monthly counts for the duration of treatment. A white blood cell count of less than 3,500/mm^3 or a granulocyte count of less than 1,500/mm^3 warrants discontinuation of the medication. Other signs of

impending marrow failure are fever, flulike symptoms, and sore throat. Discontinuation of the clozapine, supportive measures, and treatment of specific infections if identified are the main interventions for agranulocytosis, and in life-threatening cases, growth factors (filgrastim [Neupogen]) can be used.

Antidepressants

Older-generation antidepressants can cause severe adverse events, whereas the newer agents, especially the SSRIs, are remarkably safe.

Adverse events associated with tricyclic antidepressants include anticholinergic delirium, cardiac conduction delays, and seizures. Anticholinergic delirium is more common in elderly and impaired individuals and may be potentiated by concomitant anticholinergic medications. The principal intervention is to decrease or discontinue the offending agent. Furthermore, the coadministration of an SSRI or other drug known to inhibit the cytochrome P450 2D6 enzyme with a tricyclic antidepressant can cause dramatic increases in tricyclic antidepressant blood levels and resultant delirium. This can occur in a patient taking a low dose of the tricyclic antidepressant, and pharmacokinetic interactions must be considered in an emerging delirium in a patient taking what would otherwise be a safe dose of a tricyclic antidepressant. These drugs also can affect cardiac conduction, can lower seizure thresholds, and are lethal in overdose.

A hypertensive crisis can occur in a patient who is taking monoamine oxidase inhibitors. This usually happens after ingestion of a large dose of tyramine, which can be found in certain food products or after an interaction with another drug, such as meperidine, other antidepressants, and sympathomimetic agents. Discontinuation of the monoamine oxidase inhibitor and management of the hypertension are the appropriate treatments. Blood pressure control can be achieved with intravenous phentolamine or intramuscular or oral chlorpromazine.

Serotonin syndrome is a delirium characterized by altered level of consciousness, autonomic instability, and neuromuscular abnormalities including myoclonus, hyperreflexia, nystagmus, akathisia, and muscle rigidity (Martin 1996; Mason et al. 2000). Several different drugs, usually administered in combination, can cause this adverse event. Drugs reported to provoke serotonin syndrome include SSRIs, tricyclic antidepressants, monoamine oxidase inhibitors, venlafaxine, trazodone, nefazodone, lithium, tryptophan, meperidine, sumatriptan, buspirone, duloxetine, milnacipran, and amphetamines. Discontinuation of the offending agent and general supportive measures are the principal interventions. Unlike in NMS, bromocriptine can worsen the serotonin syndrome. Other drugs useful in treating this condition are benzodiazepines, cyproheptadine, chlorpromazine, methysergide, and propranolol.

Although not a life-threatening emergency, SSRI discontinuation syndrome can be very frightening and distressing to patients. This syndrome develops after abrupt discontinuation of a short-half-life SSRI, with paroxetine and venlafaxine the two most common agents. Symptoms include dizziness, malaise, nausea, paresthesias, tremor, ataxia, confusion, myoclonus, anxiety, and vivid dreaming. Symptoms usually develop 48 hours after the last dose, peak around day 4–5, and can last as long as 2 weeks. Interventions include reassuring the patient and restarting the medicine, followed by a very gradual taper. Another approach is to switch to a long-half-life agent such as fluoxetine during the final days of SSRI treatment, which will then result in a more gradual clearing of the drug and a much lower chance of provoking the discontinuation syndrome.

Priapism is a rare but potentially serious adverse event that has been associated with psychotropic medications including trazodone. This physiological condition is usually self-limiting. However, a patient with an erection lasting for more than 4 hours warrants an evaluation and treatment by appropriate medical personnel (Montague et al. 2003). Patients should be warned of this rare but serious potential side effect.

CONCLUSION

In the modern era, with changes in the mental health care delivery systems and the resultant limitations placed on the utilization of inpatient treatment resources, the emergency psychiatrist will increasingly be called upon to diagnose and initiate definitive treatment of patients with a wide range of psychiatric disorders. Emergency psychiatrists must balance the needs of individual patients with those of the larger community, the health care system, and the third-party payer system with a focus on delivering care that is both efficacious and cost-effective. This will require a broad knowledge base, incorporating elements of all branches of psychiatry, and consideration toward thorough yet expeditious evaluation, diagnosis, and treatment of patients with mental illnesses.

Chapter 63. Treatment of Child and Adolescent Disorders

TREATMENT OF CHILD AND ADOLESCENT DISORDERS: INTRODUCTION

This chapter focuses on the psychopharmacology of psychiatric disorders in children and adolescents. However, nonpharmacological treatment interventions are also an important component of a child's psychiatric care. Individual psychotherapy, group therapy, and family therapy may improve clinical outcome. Working closely with school personnel is another ingredient in the treatment of a child with a psychiatric disorder. Case management for the child and support for the family are other facets of treatment for children.

It is important for clinicians to be aware of the evidence base for the use of psychotropic medications for children and adolescents. In this chapter, data from the literature, with a focus on controlled studies, are presented. On the basis of these findings, clinical recommendations regarding pharmacotherapy for childhood psychiatric disorders are offered. The appendix and tables contain specific information about dosages, monitoring, and adverse effects of psychotropics in children.

[Portions of the Attention-Deficit/Hyperactivity Disorder section of this chapter were adapted from Wagner KD: "Management of Treatment Refractory Attention-Deficit/Hyperactivity Disorder in Children and Adolescents." *Psychopharmacology Bulletin* 36:130–142, 2002. Used with permission.]

PSYCHOTROPIC MEDICATION FOR CHILDREN AND ADOLESCENTS

Attention has been focused on the need for controlled studies to assess the safety and efficacy of psychotropic medication for children and adolescents. Although there has been a substantial increase in the use of psychotropic medications for children (Safer et al. 1996) and for preschoolers (Zito et al. 2000), there is a significant gap between empirical treatment research and clinical practice with these agents (Jensen et al. 1999). The pressing need to expand the empirical basis for the treatment of children has resulted in a substantial increase in National Institute of Mental Health (NIMH)–funded research for clinical trials in children and adolescents with psychiatric disorders (Vitiello 2001). The U.S. Food and Drug Administration Modernization Act (FDAMA) of 1997, which provides a 6-month extension of market exclusivity for selected medications for children, has resulted in a significant increase in the number of industry-sponsored studies of psychotropic medications in youths. Following this act, the U.S. Food and Drug Administration (FDA) issued "Regulations Requiring Manufacturers to Assess the Safety and Effectiveness of New Drugs and Biological Products in Pediatric Patients" (U.S. Food and Drug Administration 1998), which became effective in April 1999. This rule allows the FDA to require pediatric studies of certain new and marketed drugs, especially those that are likely to be commonly used for children. The information obtained from these studies will allow product labeling to include directions for the safe and effective use of these medications in children. To date, however, there are relatively few FDA-approved psychotropic medications for children and adolescents.

Evaluation

Prior to the initiation of psychotropic medication for children and adolescents, it is essential to conduct a comprehensive evaluation to ensure the accuracy of the diagnosis. A thorough history and careful attention to the clinical presentation are central components of the evaluation. The clinician should

interview the child and parents separately so that both may have the opportunity to freely express their concerns. Extended family members, school personnel, and school records are other potential sources of information.

Clinicians must be skilled at differential diagnosis of childhood disorders, given that there is a significant overlap of symptoms among these disorders (e.g., bipolar disorder and attention-deficit/hyperactivity disorder [ADHD]). Knowledge of commonly occurring comorbid disorders is also necessary. Medical conditions, such as seizure disorders and hypothyroidism, should be considered within the differential diagnosis and adequately assessed.

Disorder-specific rating scales at baseline and during the course of treatment may be useful in assisting with the measurement of clinical outcome.

Clinical Issues Affecting Response to Pharmacotherapy

Whenever a child fails to respond to initial pharmacotherapy, several clinical issues should be addressed before initiating alternative or adjunctive medication, as discussed below.

Diagnostic Accuracy

The diagnosis should be reassessed. Often there is symptomatic overlap among disorders that may lead to misdiagnosis. For example, symptoms of excessive energy and distractibility are common features of both ADHD and bipolar disorder. Similarly, irritability and sleep disturbance often occur in children with major depression, bipolar disorder, and posttraumatic stress disorder (PTSD).

Comorbid Disorders

Unrecognized comorbid disorders may adversely affect treatment outcome. As an illustration, children with comorbid internalizing disorders have been reported to have lower response rates to methylphenidate than children without comorbidity (Tannock et al. 1995).

Psychosocial Factors

Child abuse, domestic violence, family conflict, parental psychopathology, and bullying by peers may lead to symptoms that mimic or exacerbate a preexisting psychiatric disorder. As examples, ostracism by peers may lead to depression in a child, or a parent with depression who has a negative cognitive style may heighten the pessimistic views of a child with depression.

Medication Compliance

Some children and adolescents are reluctant to take medication because of such reasons as denial of illness, perceived stigma, and side effects. To increase medication compliance, it is essential that the child or adolescent, as well as the parent, understand the youth's disorder, course of illness, and goals of treatment. It is important for parents to participate in monitoring their child's medication compliance.

Nonpharmacological Treatment

Psychotherapy may be a component of treatment, either alone or in conjunction with medication. Specific psychotherapies have been found to be effective in the treatment of some childhood disorders. As examples, cognitive-behavioral therapy (CBT) (Brent et al. 1997) and interpersonal therapy (Mufson and Sills 2006) have demonstrated efficacy in the treatment of adolescents with depression. Similarly, CBT is commonly used for the treatment of childhood anxiety disorders (Roblek and Piacentini 2005). Behavior therapy has led to improvement in symptoms of ADHD for children (Pelham et al. 1998), although stimulants have demonstrated superiority to behavioral treatment (MTA [Multimodal Treatment of ADHD] Cooperative Group 1999). Adjunctive psychoeducation to medication treatment has shown benefit in the treatment of children with bipolar disorder (Fristad et

al. 2003). Social skills training can be a useful component of treatment in autism spectrum disorders (Krasny et al. 2003).

Informed Consent

Informed consent is necessary prior to prescribing psychotropic medication to any patient, but it is particularly important in pediatric psychopharmacology because there are few FDA-approved medications and few controlled studies to address safety and efficacy in children. There are five recommended components of informed consent for prescribing psychotropic medications to children and adolescents (Popper 1987). The child's parent(s) and the child/adolescent should be provided with the following information:

1. The purpose (benefits) of the treatment
2. A description of the treatment process
3. An explanation of the risks of the treatment, including risks that would ordinarily be described by the psychiatrist and risks that would be relevant to making the decision
4. A statement of the alternative treatments, including nontreatment
5. A statement that there may be unknown risks of these medications (This is particularly essential for children, because there is a paucity of information on the potential long-term effects of psychotropic medications.)

Evidence Base

It is important for clinicians to be aware of the evidence base for medication treatment of each childhood psychiatric disorder. Clinical treatment guidelines generally rely on the strength of the available data in determining first-line agents (Hughes et al. 2007; Kowatch et al. 2005). In most cases, clinicians should select a medication within the group of first-line agents when initiating medication treatment with a child. Additional factors that will dictate medication choice are prior medication history, medical history, side-effect profile of the drug, and adolescent and parent preferences.

MAJOR DEPRESSIVE DISORDER

The prevalence of major depression in children and adolescents is estimated to range from 1.8% to 4.6% (Kashani and Sherman 1988; Kroes et al. 2001). DSM-IV-TR (American Psychiatric Association 2000) criteria are used to establish a diagnosis of major depression in children and adolescents. The mean length of an episode of major depression in youth ranges from 8 to 13 months, and relapse rates range from 30% to 70% (Birmaher et al. 2002). There is increasing evidence for the continuity of depression from youth into adulthood (Dunn and Goodyer 2006).

Recently, a number of double-blind, placebo-controlled multicenter medication studies for treating major depression in children and adolescents have been reported. In the following subsections, medication groups are discussed in order of largest to smallest evidence base.

Selective Serotonin Reuptake Inhibitors

Fluoxetine

Fluoxetine is the only selective serotonin reuptake inhibitor (SSRI) medication to have FDA approval for the treatment of major depression in children and adolescents. There have been three positive medication trials.

In the first study of fluoxetine, 96 child and adolescent outpatients (ages 8–17 years) with major depression were randomly assigned to fluoxetine (20 mg/day) or placebo for an 8-week trial (Emslie et al. 1997). The fluoxetine group, with 27 youths (56%) much or very much improved, showed statistically significant greater improvement in Clinical Global Impressions (CGI) scores than did the placebo group, with 16 youths (33%) much or very much improved. Remission, which was defined as

a Children's Depression Rating Scale—Revised (CDRS-R; Poznanski et al. 1985) score ≤28, occurred in 31% of the fluoxetine group and 23% of the placebo group. Medication side effects leading to discontinuation in the study were manic symptoms in 3 patients and severe rash in 1 patient.

In a double-blind, placebo-controlled multicenter study of fluoxetine, 219 child and adolescent outpatients (ages 8–17 years) with major depression were randomly assigned to fluoxetine (20 mg/day) or placebo for an 8-week trial (Emslie et al. 2002). The fluoxetine group showed statistically significant greater improvement in depression, as assessed by CDRS-R scores, than did the placebo group. Fifty-two percent of patients treated with fluoxetine were rated as much or very much improved, compared with 37% of patients treated with placebo. Remission rates were 39% in the fluoxetine group and 20% in the placebo group. Headache was the only side effect that was reported more frequently in the group treated with fluoxetine than in the group treated with placebo.

Fluoxetine alone, fluoxetine with CBT, CBT alone, and placebo were compared in a multicenter trial of 439 adolescent outpatients with a diagnosis of major depression (Treatment for Adolescents with Depression Study [TADS] Team 2004). Patients were randomly assigned to 12 weeks of fluoxetine (10–40 mg/day), fluoxetine (10–40 mg/day) with CBT, CBT alone, or placebo. Compared with placebo, the combination of fluoxetine with CBT was significantly superior on CDRS-R scores. Combination treatment with fluoxetine and CBT was significantly superior to fluoxetine alone and CBT alone. Fluoxetine monotherapy was superior to CBT. Based on CGI scores of much or very much improved, the response rates were 71% for fluoxetine–CBT combination therapy, 61% for fluoxetine, 43% for CBT, and 35% for placebo. At the end of 12 weeks, only 23% of youths achieved remission (CDRS-R ≤28). Remission rates were significantly higher in the combination group (37%) than in the fluoxetine (23%), CBT (16%), and placebo (17%) groups (Kennard et al. 2006).

Citalopram

There have been two controlled trials of citalopram, one with positive and one with negative results in the treatment of depression in youth.

The efficacy of citalopram was demonstrated in a double-blind, placebo-controlled multicenter trial of 174 outpatient children and adolescents (ages 7–17 years) with major depression (Wagner et al. 2004b). Patients were randomly assigned to citalopram (dosage range = 20–40 mg/day; mean daily dose = 23 mg for children, 24 mg for adolescents) or placebo for an 8-week trial. The group treated with citalopram showed statistically significant greater improvement in depression (CDRS-R scores) than did the placebo group. The response rates (CDRS-R score <28) were 36% for patients receiving citalopram and 24% for patients receiving placebo. The most frequent adverse events were headache, nausea, rhinitis, abdominal pain, and influenza-like symptoms. The discontinuation rate for adverse events was 5% in both the group being treated with citalopram and the group receiving placebo.

A European double-blind, placebo-controlled multicenter study (Knorring et al. 2006) of citalopram in 224 adolescents with major depression failed to show superiority of citalopram to placebo on the primary efficacy measures of Schedule for Affective Disorders and Schizophrenia for School-Age Children, Present Episode version (Kiddie-SADS-P; Chambers et al. 1985) and the Montgomery-Åsberg Depression Rating Scale (MADRS; Montgomery and Asberg 1979). Interpretation of these findings is confounded by the allowed use of psychotherapy and other psychotropic medications during the course of the trial. The most commonly reported adverse events were headache, nausea, and vomiting.

Paroxetine

There have been three double-blind, placebo-controlled trials of paroxetine for treatment of depression in children and adolescents, all of which have negative findings on the primary outcome measure.

In a study of 275 adolescent outpatients (ages 12–18 years) with major depression, patients were randomly assigned to paroxetine (dosage range = 20–40 mg/day; mean daily dose = 28 mg), imipramine (dosage range = 200–300 mg; mean daily dose = 205 mg/day), or placebo for an 8-week trial (Keller et al. 2001). Although there was no statistically significant difference among the treatment groups on the primary efficacy measure of reduction in the Hamilton Rating Scale for Depression (Ham-D; Hamilton 1960) total score, there was statistically significant greater global improvement for the group receiving paroxetine. Sixty-six percent of the group receiving paroxetine was much or very much improved, compared with 52% of the group receiving imipramine and 48% of the group receiving placebo. The most common side effects reported for paroxetine were headache, nausea, dizziness, dry mouth, and somnolence, which (with the exception of somnolence) occurred at rates similar to those in the placebo group. The most common side effects reported for imipramine were dizziness, dry mouth, headache, nausea, and tachycardia.

Two hundred six children and adolescents (ages 7–17 years) with major depression were included in an 8-week double-blind, placebo-controlled, randomized multicenter study of paroxetine treatment (Emslie et al. 2006). Patients were randomly assigned to paroxetine (10–50 mg/day) or placebo. There was no statistically significant difference between paroxetine-treated patients and placebo-treated patients on change from baseline in CDRS-R total score at endpoint. Adverse events reported for paroxetine with an incidence of >5% and at least twice that of placebo were dizziness, cough, dyspepsia, and vomiting.

A 12-week international placebo-controlled multicenter trial of paroxetine in 286 adolescents with major depression failed to show superiority of paroxetine compared with placebo on change from baseline in MADRS or Schedule for Affective Disorders and Schizophrenia for School-Aged Children—Lifetime version (Kiddie-SADS-L; Kaufman et al. 1997) total scores (Berard et al. 2006).

Sertraline

The efficacy of sertraline was assessed in two identical double-blind, placebo-controlled multicenter studies of 376 outpatient children and adolescents with major depression (Wagner et al. 2003a). Patients were randomly assigned to sertraline (dosage range = 50–200 mg per day; mean daily dose = 131 mg) or placebo for a 10-week trial. The group receiving sertraline showed a statistically significant greater improvement in depression (CDRS-R scores) than did the placebo group. Response rates (decrease >40% in baseline CDRS-R scores) were 69% in the group treated with sertraline and 59% in the group treated with placebo. The most common side effects in the group treated with sertraline were headache, nausea, insomnia, upper respiratory tract infection, abdominal pain, and diarrhea. In a 24-week open follow-up of 226 of these patients, continued improvement in depressive symptoms was shown with sertraline treatment. At endpoint, 86% of youths met response criteria (Rynn et al. 2006).

Sertraline, CBT, and combined CBT plus medication were compared for the treatment of 73 adolescents with depressive disorders (Melvin et al. 2006). All treatments showed statistically significant improvement on all outcome measures; there were no significant advantages of combined treatment.

Escitalopram

There has been one controlled study of escitalopram that failed to demonstrate significant improvement on CDRS-R scores at endpoint between escitalopram and placebo (Wagner et al. 2006a). In this study, 264 children and adolescents were randomly assigned to escitalopram (10–20 mg/day) or placebo for 8 weeks. In a post hoc analysis of adolescent completers, escitalopram showed significantly improved CDRS-R scores compared with placebo. Headache and abdominal pain were the only adverse events reported in more than 10% of the patients in the escitalopram group.

Other Antidepressants

Venlafaxine

Two double-blind, placebo-controlled multicenter studies have evaluated the efficacy of venlafaxine extended-release (XR) for the treatment of major depression in 165 and 169 child and adolescent outpatients, ages 7–17 years, respectively (Emslie et al. 2007a, 2007b). Patients were randomly assigned to venlafaxine XR (37.5–225 mg/day) for 8-week trials. Both studies were negative on the primary outcome measure of change from baseline to endpoint in the CDRS-R scores. A post hoc analysis of the pooled data showed greater improvement on CDRS-R scores with venlafaxine XR for adolescents than for children. The most common adverse events were anorexia and abdominal pain (Emslie et al. 2007a). In a 6-month open-label follow-up study, it was found that most improvement with venlafaxine XR occurred in the first 6 weeks of treatment. At the end of week 6, mean CDRS-R scores decreased from 60 to 36.3, and to 33.8 at 6 months (Emslie et al. 2007b).

Nefazodone

The efficacy of nefazodone was assessed in a double-blind, placebo-controlled multicenter trial of 195 adolescents (ages 12–17 years) with major depression (Rynn et al. 2002). Adolescents were randomly assigned to nefazodone (dosage range = 300–600 mg/day; mean daily dose = 444 mg) for an 8-week trial. The nefazodone group showed greater improvement than the placebo group; however, this difference missed statistical significance ($P < 0.055$), based on the comparison of mean CDRS-R score from baseline to endpoint between the group being treated with nefazodone and the group receiving placebo. The most common side effects with nefazodone were headache, abdominal pain, nausea, vomiting, somnolence, and dizziness, all of which were reported with greater frequency in the nefazodone group than in the group receiving placebo.

In a second double-blind, placebo-controlled multicenter trial of nefazodone in both children and adolescents (ages 7–17 years) with major depression, nefazodone did not differentiate from placebo (U.S. Food and Drug Administration 2004b).

Bupropion

There are no controlled trials of bupropion for the treatment of pediatric depression.

In an 8-week study of bupropion sustained release (SR) (dosage range = 100–400 mg/day; mean daily dose = 362 mg) for treating 11 adolescents (ages 12–17 years) with major depression, 8 adolescents (79%) showed a 50% reduction in depression score from baseline (Glod et al. 2000).

Bupropion SR was assessed in an 8-week open study for the treatment of comorbid depression and ADHD in 24 adolescents (Daviss et al. 2001). Bupropion SR dosages were flexibly titrated up to 4 mg/kg taken twice daily (mean dose = 2.2 mg/kg in A.M. and 1–7 mg/kg in P.M.). Global improvement was reported for 14 subjects (58%) for both depression and ADHD, 7 subjects (29%) for depression only, and 1 subject (4%) for ADHD only. Common side effects were headache, nausea, rash, and irritability.

Mirtazapine

There have been two double-blind, placebo-controlled multicenter trials of mirtazapine for the treatment of child and adolescent outpatients (ages 7–17 years) with major depression. These studies, which included 126 and 133 patients, respectively, who were randomly assigned to mirtazapine (15–45 mg/day) or placebo for an 8-week trial, failed to distinguish mirtazapine from placebo on the primary efficacy measure of change from baseline to endpoint in CDRS-R scores (U.S. Food and Drug Administration 2004b).

Duloxetine

There are no published reports of the use of duloxetine for the treatment of major depression in children and adolescents. There are two case reports of duloxetine treatment for pediatric chronic pain and comorbid major depressive disorder (Meighen 2007) and one case report of duloxetine treatment for pediatric depression with pain and dissociative symptoms (Desarkar et al. 2006) that described improvement in depressive symptoms.

Tricyclic Antidepressants

There have been eight double-blind, placebo-controlled studies of tricyclic antidepressants (TCAs) in children and adolescents. No significant differences between TCA and placebo were found in any of these studies (Birmaher et al. 1998; B. Geller et al. 1990, 1992; Keller et al. 2001; Kutcher et al. 1994; Kye et al. 1996; Puig-Antich et al. 1987; Tancer et al. 1992). Response rates for TCA-treated patients ranged from 8% to 92% (B. Geller et al. 1990; Kye et al. 1996) and from 17% to 92% for patients treated with placebo (B. Geller et al. 1992; Kye et al. 1996). Several open trials with TCAs have reported a response rate of 60%–80% (Ambrosini et al. 1994; B. Geller et al. 1986; Preskorn et al. 1982; Puig-Antich et al. 1979).

Monoamine Oxidase Inhibitors

One chart review found a response rate of 74% in 23 adolescents treated with monoamine oxidase inhibitors (MAOIs) who had been unresponsive to TCAs. Dietary noncompliance was noted for 6 of these adolescents; 1 developed headache and hypertension, and 1 developed myoclonic jerks (Ryan et al. 1988).

Suicidality and FDA Warning

In a combined analysis of 24 short-term placebo-controlled trials of antidepressant medications in child and adolescent major depressive disorder, obsessive-compulsive disorder (OCD), or other psychiatric disorders, the risk of suicidality (suicidal thinking and behavior) was 4%, twice the placebo rate (2%). There were no suicides in any of the clinical trials. The FDA directed manufacturers to add a black box warning to the health professional label of antidepressant medications to describe the increased risk of suicidal thoughts and behavior in children and adolescents being treated with antidepressant medications and to emphasize the need for close monitoring of patients on the medications (U.S. Food and Drug Administration 2004a). Parents and patients should be advised of the black box warning for antidepressant medication.

In a subsequent meta-analysis of 27 trials of pediatric major depression, the rates of suicidal ideation and attempts were 3% in the youths treated with antidepressants and 2% in the youth who received placebo (Bridge et al. 2007). These investigators reported that the number needed to treat was 10, whereas the number needed to harm was 112, and therefore the benefits of antidepressants outweigh the potential risk from suicidal ideation or attempt.

A number of recent studies, in both the United States and Europe, have failed to demonstrate an association between antidepressant use and youth suicide (Gibbons et al. 2006; Markowitz and Cuellar 2007; Simon et al. 2006; Søndergård et al. 2006). Noteworthy, there was an increase in the suicide rate in youth following the black box warning on antidepressants (Hamilton et al. 2007). The FDA advisory has been associated with significant decreases in the rates of diagnosis and treatment in pediatric depression (Libby et al. 2007).

Clinical Recommendations for Major Depressive Disorder

An evidence-based consensus medication algorithm for the treatment of childhood major depression has been recently updated (Texas Children's Medication Algorithm Project [TMAP]; Hughes et al. 2007). Based on research evidence and panel discussion, four stages of medication treatment were identified:

- Stage 1: SSRI (fluoxetine, citalopram, sertraline)
- Stage 2: Alternate SSRI (fluoxetine, sertraline, citalopram, escitalopram, paroxetine [adolescents only if paroxetine])
- Stage 2A (if partial response to SSRI): SSRI + lithium, bupropion, or mirtazapine
- Stage 3: Different class of antidepressant medication (venlafaxine, bupropion, mirtazapine, duloxetine)
- Stage 4: Reassess, treatment guidance

If a child fails to respond to treatment in one stage, the clinician should move to the next stage of treatment. It was recommended by the consensus panel that dosage titration should occur in youths who do not have significant improvement in symptoms by 4–6 weeks of treatment. Additional dose adjustments should be made at 8–10 weeks of treatment before moving to another stage of treatment.

It was further recommended that antidepressants be continued for 6–12 months after symptom remission. At the time of discontinuation of an antidepressant, the dose should be tapered slowly (i.e., no more than 25% per week). The typical tapering and discontinuation period is 2–3 months.

BIPOLAR DISORDER

The prevalence of bipolar disorder in a community sample of adolescents was found to be 1% (Lewinsohn et al. 1995). Although DSM-IV-TR criteria are used to diagnose bipolar disorder in youths, the clinical features in children may differ from those in adolescents and adults. Children with bipolar disorder frequently exhibit mixed mania and rapid cycling (B. Geller et al. 2000). One-year recovery rates of 87% and relapse rates of 64% have been reported in children with bipolar disorder (B. Geller et al. 2004). Despite the severity of bipolar disorder and its significant adverse effects on a child's social, emotional, and academic functioning, it has yet to be determined whether pharmacotherapy alters the course of the illness (Birmaher et al. 2006).

Lithium

Lithium is the only medication with FDA approval for the treatment of mania in adolescents.

There is only one small double-blind, placebo-controlled study of lithium treatment for adolescent bipolar disorder and substance dependence (B. Geller et al. 1998). Twenty-five adolescent outpatients were randomly assigned to either lithium (mean serum level = 0.97 mEq/L) or placebo for a 6-week trial. There was significantly greater improvement in global functioning with lithium than with placebo. It was found that onset of bipolar disorder preceded substance dependence by approximately 6 years. Side effects in the group treated with lithium were polyuria, thirst, nausea, vomiting, and dizziness.

There have been six controlled studies of lithium in the treatment of bipolar disorder in youths. In four of these double-blind crossover studies, significant improvement was found with lithium, compared with placebo (DeLong and Nieman 1983; Gram and Rafaelsen 1972; Lena 1979; McKnew et al. 1981). However, small sample size, diagnostic issues, and short treatment duration limit these findings.

In a 4-week open trial, 100 adolescents with mania received lithium (mean serum level 0.93 mEq/L) (Kafantaris et al. 2003). Forty-six of these youths also received concomitant antipsychotic medication. The lithium response rate was 55%, based on a ≥50% reduction in Young Mania Rating Scale (YMRS; Young et al. 1978) scores. The most common side effects were polydipsia, polyuria, weight gain, gastrointestinal symptoms, headache, and tremor.

Kafantaris et al. (2004) conducted a controlled discontinuation study with 40 adolescents who had responded to lithium in the open trial. Responders were randomly assigned to continue or discontinue lithium during a 2-week double-blind, placebo-controlled phase. There was no statistically significant difference on symptom exacerbation rate between the lithium (52.6%) and placebo (61.9%) groups. The investigators concluded that 4 weeks of lithium monotherapy may be insufficient for symptom remission in adolescents.

The efficacy of lithium, divalproex, and carbamazepine was compared in a 6-week randomized, open-label trial of 42 children and adolescents (ages 8–18 years) with bipolar disorder (Kowatch et al. 2000b). There were no significant differences in response rates (defined as ≥50% reduction in YMRS from baseline to endpoint) among lithium, divalproex, and carbamazepine. The lithium response rate was 38%, and the effect size was 1.06.

Lithium treatment for adolescents with bipolar depression was investigated in a 6-week open study of 27 adolescents. The response rate (≥50% reduction in baseline CDRS-R score) was 48% (Patel et al. 2006).

Anticonvulsants

Divalproex

A 4-week double-blind, placebo-controlled multicenter trial of 150 youths (ages 10–17 years) with bipolar I disorder (mixed or manic) failed to show a significant difference in scores on the YMRS from baseline to endpoint between divalproex extended release (ER) and placebo (Abbott Laboratories, accessed 2007). The mean modal dose of divalproex ER was 1,286 mg. There were no statistically significant differences in adverse-event incidents between the divalproex ER and placebo groups. Gastrointestinal symptoms were more commonly reported in divalproex ER than in placebo groups.

In a multisite open study of divalproex treatment for youths, 40 children and adolescents (ages 7–19 years) with bipolar disorder received divalproex for a period of 2–8 weeks (Wagner et al. 2002). Sixty-one percent of the subjects showed >50% improvement on the YMRS from baseline to endpoint. Twenty-three patients (58%) discontinued the study; of those, 16 patients had a comorbid diagnosis, including ADHD, conduct disorder, or oppositional defiant disorder (ODD). Headache, nausea, vomiting, diarrhea, and somnolence were the most common side effects.

In the previously mentioned active-comparator study of lithium, divalproex, and carbamazepine, the response rate (≥50% reduction in baseline YMRS scores) was 53% for divalproex. The effect size for divalproex was 1.63. The most common side effects of divalproex were nausea and sedation (Kowatch et al. 2000b).

The efficacy of divalproex was compared with that of quetiapine in 50 hospitalized adolescents with bipolar I disorder, manic or mixed (DelBello et al. 2006). Twenty-five adolescents were randomly assigned to divalproex (serum level 80–120 μg/mL) or quetiapine (400–600 mg/day). There were no significant differences between divalproex and quetiapine across the 28 days of the study. The CGI-BP-I overall response rate (CGI-BP-I overall score ≤2 at endpoint) was 40%, and the CGI-BP-I mania response rate was 56% for divalproex, which were significantly lower than the rates for quetiapine. The rate of remission (YMRS ≥12) for divalproex was 28%.

Carbamazepine

In a 6-week active-comparator study of lithium, divalproex, and carbamazepine (Kowatch et al. 2000b), carbamazepine had a response rate (defined as ≥50% reduction in YMRS from baseline to endpoint) of 38% (vs. 38% for lithium and 53% for divalproex) and an effect size of 1.00 (vs. 1.6 for lithium and 1.63 for divalproex). The most common side effects of carbamazepine were sedation, nausea, dizziness, and rash.

Oxcarbazepine

There is one double-blind, placebo-controlled multicenter trial of oxcarbazepine for the treatment of youths with bipolar I disorder, manic or mixed, that failed to show superiority of oxcarbazepine to placebo. One hundred sixteen youths (ages 7–18 years) were randomly assigned to oxcarbazepine (mean dosage = 1,515 mg/day) or placebo for a 7-week trial (Wagner et al. 2006b). There was no

significant difference in YMRS scores at endpoint between the oxcarbazepine and placebo groups. The most common side effects in the oxcarbazepine-treated patients were dizziness, nausea, somnolence, diplopia, fatigue, and rash.

Topiramate

A double-blind, randomized, placebo-controlled multicenter study assessing the efficacy of topiramate treatment in children and adolescents with acute mania was designed as a 200-patient study but was terminated after randomizing 56 patients (ages 6–17 years) when adult mania trials failed to show efficacy (DelBello et al. 2005). Patients were titrated to 400 mg/day (mean dosage = 278 mg/day). Over a 4-week period, no significant difference was found between the topiramate and placebo groups. The most common adverse events in the topiramate group included decreased appetite, nausea, diarrhea, paresthesias, and somnolence.

Lamotrigine

In a 12-week open-label single-center outpatient study in adolescents diagnosed with bipolar disorder I, depressed or mixed, 23 patients entered, and 13 completed the trial (Swope et al. 2004). The mean dosage of lamotrigine was 241 mg/day. There was improvement on depression and mania ratings at study endpoint. No subjects discontinued for adverse events related to the study drug.

Lamotrigine as monotherapy or adjunctive treatment for 20 adolescents with bipolar depression was assessed in an 8-week open-label trial (Chang et al. 2006). The mean dosage of lamotrigine was 132 mg/day. Seven adolescents were also taking other psychotropic medications. The response rate (CGI-I ≤2) was 84%, and the remission rate (CDRS-R ≤28 and CGI-S ≤2) was 58%. The most common side effects were headache, fatigue, nausea, sweating, and difficulty sleeping. There were no significant rashes during the trial.

The use of lamotrigine as adjunctive therapy for treatment-refractory bipolar depression in adolescents was assessed in an open-label study (Kusumakar and Yatham 1997). Twenty-two adolescents whose bipolar depression was refractory to treatment with a combination of divalproex plus another mood stabilizer and antidepressant were treated with lamotrigine added to divalproex for 6 weeks. Sixteen of the adolescents (72%) had a positive response by week 6.

Atypical Antipsychotics

Olanzapine

There is one reported double-blind, placebo-controlled multicenter study of olanzapine (2.5–20 mg/day) for the treatment of adolescent outpatients with bipolar I disorder, mixed or manic (Tohen et al. 2007). Adolescents were randomly assigned to olanzapine (n = 107) or placebo (n = 54) for 3 weeks. Response rates (defined as ≥50% decrease in YMRS and a CGI-BP mania score ≤3) were significantly greater for the olanzapine group (44.8%) than for the placebo group (18.5%). Remission rates (defined as YMRS <12 and CGI-BP mania score ≤3) were significantly greater for the olanzapine (35.2%) than for the placebo (11.1%) group. Adverse effects in the olanzapine group were hyperprolactinemia, weight gain (mean = 3.7 kg), somnolence, and sedation.

In an open study, 23 children (ages 5–14 years) with bipolar disorder received olanzapine (2.5 mg/day) for 8 weeks (Frazier et al. 2001). Using a response definition of 30% or greater improvement on the YMRS, the response rate was 61%. No significant side effects except weight gain (mean = 5 kg) were reported.

The use of olanzapine in preschoolers is an area of recent interest. An 8-week open-label study of olanzapine and risperidone in children (ages 4–6 years) with bipolar disorder (manic, mixed, or hypomanic) was conducted by Biederman et al. (2005b). Fifteen children were treated with

olanzapine (mean dosage = 6.3 mg/day). The response rate (CGI-I ≤2 or YMRS reduction ≥30%) was 53% for olanzapine. Mean weight increase was 3.2 kg for olanzapine-treated children. The most common side effects of olanzapine were increased appetite, cold symptoms, headache, and sedation.

Risperidone

There are no data available from controlled trials of risperidone for the treatment of bipolar disorder in youth.

An 8-week open-label study of risperidone (mean dosage = 1.25 mg/day) for 30 youths (ages 6–17 years) with bipolar disorder (manic, mixed, or hypomanic) was conducted by Biederman et al. (2005c). Twenty-two of 30 youths completed the study. The response rate (CGI-I in mania score ≤2 at endpoint) was 70%. Significant side effects included weight increase (mean 2.1 kg) and a fourfold increase in prolactin levels from baseline.

In the previously mentioned open-label study of preschoolers with bipolar disorder (Biederman et al. 2005b), 16 children received risperidone (mean dosage = 1.4 mg/day). The response rate (CGI-I ≤2 or YMRS reduction of ≥30%) was 69% in the risperidone group. Weight increase was a mean of 2.2 kg in the risperidone-treated children. The most common side effects were increased appetite, cold symptoms, headaches, and sedation.

Quetiapine

The efficacy of quetiapine was compared with divalproex in 50 hospitalized adolescents with bipolar I disorder, manic or mixed (DelBello et al. 2006). Twenty-five adolescents were randomly assigned to quetiapine (400–600 mg/day). There was no statistically significant difference in YMRS scores across the 28 days of the study between quetiapine and divalproex. Response rates of 72% (CGI-BP-I overall score ≤2) and of 84% (CGI-BP-I mania score ≤2) for quetiapine were significantly higher than those for divalproex. The rate of remission (YMRS ≤12) was 60% in the quetiapine group. Improvement occurred more rapidly in the quetiapine group than in the divalproex group.

Aripiprazole

There are no published controlled studies of aripiprazole treatment for bipolar disorder in children and adolescents.

Three chart reviews reported clinical global improvement in symptoms for youth with bipolar disorder who were treated with aripiprazole (Barzman et al. 2004; Biederman et al. 2005a; Gibson et al. 2007).

Ziprasidone

There are no data available from controlled trials of ziprasidone for the treatment of bipolar disorder in youth.

In a study of 30 children and adolescents with bipolar disorder given open-label ziprasidone (mean dosage = 56 mg/day) for a mean treatment duration of 359 days, 70% of patients responded to ziprasidone (CGI-I score of much or very much improved) (Barnett and Cohen 2004).

The comparative efficacy of atypical antipsychotics was assessed in youths with mania (Biederman 2005). In this study, 21 youths received ziprasidone (mean dosage = 56 mg/day) in an 8-week open-label trial. There were significant reductions in YMRS scores for all atypical antipsychotics, with no significant difference among them. The CGI ≤2 response rate was 57% for ziprasidone. Mean weight gain was 0.6 kg for ziprasidone.

Combination Treatment

Some children may not respond to initial monotherapy treatment or may need combination treatment over the course of the illness. For example, following acute 6-week treatment with one mood

stabilizer, Kowatch et al. (2000a) reported that 20 of 35 youths (58%) required additional psychotropic medication over the next 16 weeks. The response rate to combination treatment with two mood stabilizers was high (80%) for those youths who did not respond to monotherapy.

The effectiveness of combination lithium and divalproex sodium was assessed in an open trial (Findling et al. 2003a). Ninety youths (ages 5–17 years) with bipolar I or II disorder were treated for up to 20 weeks with divalproex sodium (mean blood level = 79.8 μg/mL) and lithium (mean blood level = 0.9 mmol/L). The clinical remission rate (defined as contiguous weekly ratings of YMRS ≤12.5, CDRS-R ≤40, Children's Global Assessment Scale [CGAS] ≥51, clinical stability, and no mood cycling) was 42%.

Lithium and adjunctive haloperidol were used to treat five adolescents with psychotic mania (Kafantaris et al. 2001b). In this trial, haloperidol was discontinued within 1 week of therapeutic lithium levels. All these adolescents had a rapid return to symptoms, which responded to restarting haloperidol.

In a larger open trial (Kafantaris et al. 2001a), 28 acutely manic adolescents with psychotic features received combination lithium and antipsychotic medication for 4 weeks. At the end of 4 weeks, only 14 (50%) were clinically stable enough to have the antipsychotic medication discontinued. On lithium monotherapy, 8 adolescents remained stable over a 4-week period, and 6 adolescents had an exacerbation of symptoms. These investigators concluded that adjunctive antipsychotic medication needs to be continued for more than 4 weeks for most adolescents with psychotic mania.

The efficacy of combination risperidone and lithium or divalproex sodium was assessed in a 6-month open-label trial (Pavuluri et al. 2004). Thirty-seven youths (ages 5–18 years) with bipolar I disorder (manic or mixed) received risperidone (mean dosage = 0.75 mg) plus divalproex sodium (mean serum level = 106 μg/mL) or risperidone (mean dosage = 0.70 mg) plus lithium (mean serum level = 0.9 mEq/L). Response rates (≥50% reduction in baseline YMRS scores) were similar for both combinations: 80% for divalproex sodium plus risperidone, and 82.4% for lithium plus risperidone. There were no significant differences between the groups in safety and tolerability.

Risperidone augmentation of lithium nonresponders was assessed in a 1-year open-label study (Pavuluri et al. 2006). Twenty-one of 38 youths (ages 4–17 years) who failed to respond to lithium monotherapy or relapsed after initial response were given risperidone (mean dosage = 0.99 mg) for 11 months. Response rates in the lithium plus risperidone group were 85.7%.

In a double-blind, placebo-controlled study of quetiapine, 30 adolescents with bipolar disorder received divalproex (20 mg/kg) and were randomly assigned to adjunctive quetiapine (mean daily dose = 432 mg) or placebo for 6 weeks (DelBello et al. 2002). Response rates (YMRS reduction from baseline ≥50%) were significantly higher in the group receiving divalproex and quetiapine (87%) than in the group receiving divalproex and placebo (53%).

Maintenance Treatment

There is only one reported maintenance study for children and adolescents with bipolar disorder. Sixty youths who had responded to a combination of lithium and divalproex in a 20-week trial were randomly assigned in a double-blind trial to either lithium or divalproex for 18 months (Findling et al. 2005). There was no significant difference in the time to relapse between the groups (median days: divalproex 112, lithium 114).

Clinical Recommendations for Bipolar Disorder

Treatment guidelines were developed by expert consensus and review of the available treatment literature for children and adolescents (ages 6–17 years) with bipolar I disorder, manic or mixed (Kowatch et al. 2005). Six stages were identified:

- Stage 1: Monotherapy with mood stabilizer or atypical antipsychotic (lithium, valproate, carbamazepine, olanzapine, quetiapine, risperidone)
- Stage 2: Switch monotherapy agent (drug class not tried in stage 1)
- Stage 3: Switch monotherapy agent (drug class not tried in stage 1 or 2) OR combination treatment (2 agents)
- Stage 4: Combination treatment (2 agents) OR combination treatment (3 agents)
- Stage 5: Alternative monotherapy (drugs not tried in stages 1, 2, 3)
- Stage 6: Electroconvulsive therapy (adolescents) or clozapine

If a child fails to respond to treatment in one stage, the clinician should move to the next stage of treatment. For treatment of bipolar I disorder, manic or mixed with psychosis, it was recommended that initial treatment be a mood stabilizer plus an atypical antipsychotic. A minimum of 4–6 weeks at therapeutic blood levels and/or adequate doses for each medication was recommended. Following sustained remission of at least 12–24 months, medication taper should be considered.

ANXIETY DISORDERS

Obsessive-Compulsive Disorder

OCD has a prevalence rate of 2%–4% in youths (Douglass et al. 1995; Zohar 1999). The DSM-IV-TR criteria for OCD are the same in children and adults, with the exception that children may not recognize that their obsessions or compulsions are unreasonable (American Psychiatric Association 2000). The course of OCD in youths is chronic. In a 2- to 7-year follow-up of 54 children and adolescents with OCD, 23 subjects (43%) continued to meet diagnostic criteria for OCD, and only 3 subjects (6%) achieved complete remission (Leonard et al. 1993).

Serotonin Reuptake Inhibitors

Four medications have received FDA approval for the treatment of OCD in children and adolescents: clomipramine (≥10 years old), fluvoxamine (≥7 years old), sertraline (≥6 years old), and fluoxetine (≥7 years old).

Fluvoxamine

The safety and efficacy of fluvoxamine were evaluated in a double-blind, placebo-controlled multicenter study (Riddle et al. 2001). One hundred twenty outpatient children and adolescents (ages 8–17 years) with OCD were randomly assigned to fluvoxamine (dosage range = 50–200 mg/day; mean daily dose = 165 mg) or placebo for a 10-week trial. Patients who did not respond after 6 weeks could discontinue the double-blind phase and enter an open-label trial of fluvoxamine. Mean CY-BOCS scores were significantly different between the group treated with fluvoxamine and the group treated with placebo at weeks 1, 2, 3, 4, 6, and 10. Response rates (>25% reduction in CY-BOCS scores) were 42% in the group being treated with placebo. Adverse events occurring at a placebo-adjusted frequency of >10% were insomnia and asthenia.

To assess the safety and effectiveness of fluvoxamine in the long-term treatment of pediatric OCD, 99 patients who completed the acute double-blind, placebo-controlled fluvoxamine study (Riddle et al. 2001) participated in a 1-year open-label extension study (Walkup et al. 1998). Fluvoxamine dosages were titrated to 200 mg/day over the first 4 weeks. Patients experienced a 42% reduction in CY-BOCS scores by the end of long-term treatment. Clinical improvement plateaued at about 6 months of treatment. The most common side effects were insomnia, asthenia, nausea, hyperkinesias, and nervousness. There were no clinically significant laboratory or vital sign abnormalities.

Sertraline

In a double-blind, placebo-controlled multicenter study, 187 children and adolescents (ages 6–17 years) with OCD were randomly assigned to sertraline or placebo (March et al. 1998). Sertraline

dosages were titrated to a maximum of 200 mg/day during the first 4 weeks of the trial, and these dosages were maintained for an additional 8 weeks. The mean dosage of sertraline was 167 mg/day at endpoint. Compared with patients receiving placebo, patients receiving sertraline showed significantly greater improvement on the CY-BOCS, the NIMH Global Obsessive Compulsive Rating Scale (NIMH GOCS), and the Clinical Global Impression Severity of Illness (CGI-S) and Improvement (CGI-I) rating scales. Forty-two percent of patients in the sertraline group and 26% of patients in the placebo group were rated as very much or much improved. Side effects of insomnia, nausea, agitation, and tremor occurred significantly more often in the group receiving sertraline than in the group receiving placebo.

To assess the long-term safety and effectiveness of sertraline for pediatric OCD, 137 patients who completed the 12-week double-blind, placebo-controlled sertraline study (March et al. 1998) were given open-label sertraline (mean dosage = 120 mg/day) in a 52-week extension study. Significant improvement was found on CY-BOCS, NIMH GOCS, and CGI scores. Rates of response (defined as >25% decrease in CY-BOCS and a CGI-I score of 1 or 2) were 72% for children and 61% for adolescents (Cook et al. 2001). Full remission (defined as a CY-BOCS score >8) was achieved in 47% of patients, and an additional 25% achieved partial remission (CY-BOCS score <15 but >8) (Wagner et al. 2003b). The most common side effects were headache, nausea, diarrhea, somnolence, abdominal pain, hyperkinesias, nervousness, dyspepsia, and vomiting. There were no clinically significant electrocardiogram (ECG), vital sign, or laboratory abnormalities.

The relative and combined efficacy of sertraline and CBT was assessed in a 12-week trial for 112 children and adolescents (ages 7–17 years) with OCD (Pediatric OCD Treatment Study [POTS] Team 2004). Patients were randomly assigned to sertraline, CBT, combined sertraline and CBT, or placebo. Combined treatment was significantly superior to CBT alone and sertraline alone, which did not differ from each other.

Group cognitive-behavioral therapy (GCBT) was compared with sertraline treatment for OCD in a randomized trial with 40 youths (ages 9–17 years) (Asbahr et al. 2005). Both GCBT and sertraline yielded significant improvement in CY-BOCS scores after 12 weeks of treatment. After a 9-month follow-up period, GCBT-treated patients had a significantly lower rate of relapse compared with the sertraline-treated group (5.3% vs. 50%, respectively).

Paroxetine

The efficacy and safety of paroxetine were assessed in a double-blind, placebo-controlled multicenter study of 203 outpatient children and adolescents (ages 7–17 years) with OCD (D. A. Geller et al. 2004). Patients were randomly assigned to paroxetine (dosage range = 10–50 mg/day; mean daily dose = 23 mg) or placebo for a 10-week trial. There was a statistically significant greater reduction in CY-BOCS scores from baseline to endpoint in patients treated with paroxetine than in patients treated with placebo. Response rates (>25% reduction in CY-BOCS scores) were 64.9% in the paroxetine-treated patients and 41.2% in the placebo-treated patients. The most common adverse effects in the paroxetine group were headache, abdominal pain, nausea, respiratory disorder, somnolence, hyperkinesias, and trauma.

The efficacy of paroxetine in 335 outpatients (ages 7–17 years) with OCD was assessed in a 16-week open-label multicenter study of paroxetine (10–60 mg/day), followed by double-blind randomization of responders to paroxetine or placebo for an additional 16 weeks (Emslie et al. 2000). The rate of response (defined as >25% reduction in CY-BOCS scores) was 68.7% in the open-label phase. No significant differences in response rates were found between the group receiving paroxetine and the group receiving placebo in the randomization phase. However, fewer patients receiving paroxetine relapsed than did patients receiving placebo (34.7% and 43.9%, respectively).

A post hoc analysis of the study by Emslie et al. (2000) found that the response rates in patients with

comorbid ADHD, tic disorder, or ODD (56%, 53%, and 39%, respectively) were significantly lower than those in patients without comorbid disorders (75%). Behavioral adverse events, such as insomnia, nervousness, and hyperkinesia, were also significantly more frequent in patients with psychiatric comorbidity (D. A. Geller et al. 2001a).

Fluoxetine

The safety and efficacy of fluoxetine were assessed in a 13-week double-blind, placebo-controlled multicenter trial (D. A. Geller et al. 2001b). One hundred three children and adolescents (ages 7–17 years) with OCD were randomly assigned in a 2:1 ratio to either fluoxetine (dosage range = 10–60 mg/day; mean daily dose = 24.6 mg) or placebo. The group treated with fluoxetine showed a statistically significant reduction in OCD severity compared with the group treated with placebo, as assessed by CY-BOCS scores. Rates of response (defined as >40% reduction in CY-BOCS score) were 49% in the fluoxetine group and 25% in the placebo group. There were no significant differences in treatment-emergent adverse events between the fluoxetine and placebo groups. There were significant differences for change in weight and blood pressure between the groups, in the direction of mild weight loss and slight decrease in blood pressure for the fluoxetine group.

In post hoc subgroup analyses of the study by D. A. Geller et al. (2001b), no predictive factors in response to fluoxetine treatment for pediatric OCD were found (D. A. Geller et al. 2001c). There were no statistically significant differences in treatment effect between children vs. adolescents, females vs. males, patients with vs. without a family history of depression or OCD, or patients with age at onset <7 years vs. ≥7 years.

Fluoxetine was compared with placebo in a controlled trial in 43 youths with OCD (Liebowitz et al. 2002). It was found that after 16 (but not 8) weeks of treatment, the fluoxetine group had significantly lower CY-BOCS scores than the placebo group. These investigators concluded that fluoxetine's full effect took longer than 8 weeks to develop.

In a smaller double-blind crossover trial of fixed-dosage fluoxetine (20 mg/day) and placebo, 14 children and adolescents (ages 8–15 years) with OCD participated in a 20-week trial with crossover at 8 weeks (Riddle et al. 1992). CY-BOCS scores decreased significantly more after 8 weeks of treatment with fluoxetine than after treatment with placebo (44% and 27%, respectively). The most frequently reported side effects were insomnia, fatigue, motoric activation, and nausea.

Citalopram

Twenty-three child and adolescent outpatients (ages 9–18 years) with OCD were administered open-label citalopram (dosage range = 10–40 mg/day; mean daily dose = 37 mg) in a 10-week trial (Thomsen 1997). There was a statistically significant improvement in CY-BOCS scores from baseline to endpoint. Over 75% of youths showed a moderate to marked improvement in OCD symptoms. Adverse effects were minimal and transient.

In an 8-week open-label citalopram study of 15 youths (ages 6–17 years) with OCD, 14 patients showed significant improvement in CY-BOCS scores from baseline to endpoint. Sedation (n = 1) and insomnia (n = 1) were reported in the first week of treatment (Mukaddes and Abali 2003).

In a long-term, open study of 30 adolescents with OCD, citalopram (dosage range = 20–70 mg/day; mean daily dose = 46.5 mg) was administered for 1–2 years (Thomsen et al. 2001). There was a significant reduction in CY-BOCS scores from baseline to assessment at 2 years. No serious adverse events were reported, and the most common side effects were sedation, sexual dysfunction, and weight gain.

Clomipramine

Clomipramine has been shown to be efficacious in the treatment of pediatric OCD in two double-blind,

placebo-controlled trials. In the first study (Flament et al. 1985), 19 children (ages 10–18 years) with OCD were randomly assigned to clomipramine (dosage range = 100–200 mg/day; mean daily dose = 141 mg) or placebo for 5 weeks. Significant improvement in observed and self-reported obsessions and compulsions was found for patients who received clomipramine. The most common side effects were tremor, dry mouth, dizziness, and constipation. One patient had a grand mal seizure.

In an 8-week double-blind, placebo-controlled multicenter study of 60 children and adolescents (ages 10–17 years) with OCD, it was found that patients who received clomipramine (up to 200 mg/day) had significantly greater reductions in scores on the Children's Yale-Brown Obsessive Compulsive Scale (CY-BOCS; Goodman et al. 1991) compared with the placebo group (37% and 8%, respectively). Forty-seven patients continued in a 1-year open-label extension trial, and effectiveness was maintained with long-term treatment. The most frequent side effects were dry mouth, somnolence, dizziness, fatigue, tremor, headache, constipation, and anorexia (DeVeaugh-Geiss et al. 1992).

In a 10-week double-blind crossover trial of clomipramine and desipramine for 48 children and adolescents (ages 7–19 years) with OCD, clomipramine was shown to be significantly superior to desipramine in reducing obsessive-compulsive symptoms (Leonard et al. 1989). Sixty-four percent of patients who received clomipramine as their first active treatment showed some signs of relapse during treatment with desipramine.

Leonard et al. (1991) further assessed whether patients who were maintained on long-term clomipramine would relapse following double-blind desipramine substitution. Twenty-six children and adolescents with OCD who received maintenance treatment (mean duration = 17.1 months; range = 4–32 months) entered an 8-month double-blind desipramine substitution trial. Eight of 9 patients (89%) in the desipramine group and 2 of 11 patient (18%) in the clomipramine group relapsed during the comparison period.

Anxiolytics

Buspirone

In a case report of an 11-year-old girl with treatment-refractory OCD, buspirone (up to 300 mg/day) over a 3-week period was noted to produce a substantial reduction in obsessive-compulsive symptoms (Alessi and Bos 1991).

Benzodiazepines

A case report of a 14-year-old boy with OCD who received clonazepam (up to 2 mg/day) found a marked decrease in obsessive-compulsive symptoms over an 11-week period (Ross and Pigott 1993). A 16-year-old boy with OCD who had failed to respond to prior trials of clomipramine, fluoxetine, fluvoxamine, and buspirone augmentation showed a 75% improvement in obsessive-compulsive symptoms when his fluoxetine dosage (60 mg/day) was augmented with clonazepam (4 mg/day) (Leonard et al. 1994).

Atypical Antipsychotic Augmentation

Adjunctive risperidone (≤2 mg daily) was investigated in an open trial for 17 adolescents with OCD who failed to respond to two serotonin reuptake inhibitor monotherapy trials. A significant reduction in CY-BOCS scores was reported (Thomsen 2004).

Aripiprazole augmentation of CBT was found to be effective in the case of an adolescent who had a partial response to combined CBT and sertraline (Storch et al. 2008).

Generalized Anxiety Disorder

The prevalence of generalized anxiety disorder (GAD) in children and adolescents is estimated to

range from 2.9% to 7.3% (J. C. Anderson et al. 1987; Kashani and Orvaschel 1988). Children with GAD have excessive anxiety and worry about several events or activities (e.g., school performance), have difficulty controlling the worry, and have at least one associated symptom, such as restlessness, fatigue, concentration difficulties, irritability, muscle tension, and sleep disturbance (American Psychiatric Association 2000). Most symptoms of childhood overanxious disorder were subsumed within GAD. Therefore, overanxious disorder was eliminated from DSM-IV (American Psychiatric Association 1994). The course of GAD in youths tends to be chronic (Keller et al. 1992).

Venlafaxine

The efficacy and safety of venlafaxine XR were evaluated in an 8-week double-blind, placebo-controlled multicenter trial (Kunz et al. 2002). One hundred fifty-eight children and adolescents (ages 6–17 years) with GAD were randomly assigned to venlafaxine XR (dosage range = 37.5–225 mg/day) or placebo. There was a statistically significant greater reduction in anxiety scores in the venlafaxine XR group compared with the placebo group. Forty-nine patients (64%) receiving venlafaxine were much or very much improved, compared with five patients (6%) receiving placebo. The most common treatment-related adverse events were hyperkinesia, somnolence, and epistaxis.

Sertraline

Twenty-two children and adolescents (ages 5–17 years) with GAD were randomly assigned to sertraline or placebo in a 9-week double-blind trial (Rynn et al. 2001). The maximum dosage of sertraline was 50 mg/day. Significant differences in favor of sertraline over placebo were observed on Hamilton Anxiety Scale (Ham-A; Hamilton 1959) scores and on CGI-S and CGI-I ratings. Side effects found to be more common (but not statistically significant so) with sertraline than with placebo were dry mouth, drowsiness, leg spasm, and restlessness.

Buspirone

There have been two open studies of buspirone for the treatment of GAD in youths. In an open study of adolescents with GAD, a significant decrease in anxiety clinical ratings after 6 weeks of treatment with buspirone (mean dosage range = 15–30 mg/day) was reported (Kutcher et al. 1992). Simeon (1993) reported the results of an open trial of buspirone for 13 children with anxiety disorders; 9 of these patients had DSM-III-R (American Psychiatric Association 1987) overanxious disorder as a primary or secondary diagnosis. Patients received buspirone (maximum dosage = 30 mg/day) over 4 weeks. Significant improvement in anxiety was found on clinical ratings and parent, teacher, and patient reports. Mild and transient side effects were reported, including sleep difficulties, tiredness, nausea, stomachaches, and headaches.

Benzodiazepines

A few studies have demonstrated some effectiveness of high-potency benzodiazepines in treating children and adolescents with GAD. Twelve patients (ages 8–16 years) with a DSM-III-R diagnosis of overanxious disorder or avoidant disorder received alprazolam (maximum dosage = 0.5–1.5 mg/day) in a 4-week open trial (Simeon and Ferguson 1987). Significant improvement in anxiety was found on clinical ratings and parent questionnaires. Parental reports indicated a decrease in the frequency and severity of sleep problems. The most commonly reported adverse effects were initial daytime sleepiness, agitation, headaches, and nausea. No significant changes in blood pressure, pulse, or respiration were observed.

This open study was followed by a double-blind, placebo-controlled study of alprazolam in the treatment of 30 children (ages 8–16 years) with a DSM-III-R diagnosis of overanxious disorder (n = 21) or avoidant disorder (n = 9) (Simeon et al. 1992). Patients were randomly assigned to alprazolam (dosage range = 0.5–3.5 mg/day; mean daily dose = 1.57 mg) or placebo for a 4-week trial. On the basis of global ratings of improvement, alprazolam was superior to placebo, but this difference was

not statistically significant. Side effects were mild and included dry mouth and fatigue. No rebound or withdrawal symptoms occurred, and no adverse cognitive effects were noted.

Social Anxiety Disorder

The prevalence of social anxiety disorder (social phobia) is estimated to range from 0.9% to 7% of children and adolescents (J. C. Anderson et al. 1987; Stein et al. 2001). The diagnostic criteria for social anxiety disorder in children and adolescents are the same as the diagnostic criteria used in adults (American Psychiatric Association 2000). Social anxiety disorder in youths is a chronic condition, and it increases the risk of depression (Stein et al. 2001). Social anxiety disorder during adolescence has been shown to persist into adulthood (Pine et al. 1998).

Selective Serotonin Reuptake Inhibitors

Paroxetine

The efficacy and safety of paroxetine were evaluated in a 16-week double-blind, placebo-controlled multicenter trial in 322 outpatient children and adolescents (ages 8–17 years) with social anxiety disorder (Wagner et al. 2004a). Paroxetine was significantly superior to placebo, with rates of response (defined as CGI-I score = 1 or 2) of 77.6% and 38.3%, respectively. Side effects more common with paroxetine than with placebo were insomnia, decreased appetite, and vomiting.

Sertraline

Fourteen outpatient children and adolescents (ages 10–17 years) with a diagnosis of social anxiety disorder received sertraline (dosage range = 100–200 mg/day; mean daily dose = 123 mg) in an 8-week open trial (Compton et al. 2001). Five of the patients (36%) were much or very much improved, and four of the patients (29%) had a partial response by the end of the 8-week trial. A significant clinical response was noted by week 6. Sertraline was well tolerated, and no patient developed significant behavioral disinhibition or mania (Compton et al. 2001).

Citalopram

Chavira and Stein (2002) investigated the effectiveness of a combined psychoeducational and pharmacological treatment program for youths with social anxiety disorder. Twelve children and adolescents (ages 8–17 years) with social anxiety disorder received citalopram (mean daily dose = 35 mg) and eight 15-minute counseling sessions over a 12-week period. On the basis of clinical global ratings of change, 41.7% of youths (*n* = 5) were very much improved, and 41.7% of youths (*n* = 5) were much improved.

Nefazodone

A 15-year-old boy with social anxiety who was treated with nefazodone (up to 350 mg/day) over a 5-month period had resolution of social anxiety symptoms (Mancini et al. 1999).

Buspirone

A 16-year-old boy with social anxiety disorder and a mixed personality disorder with predominantly schizotypal features was treated with buspirone (up to 20 mg/day). At the end of 12 days of buspirone treatment, he was noted to have a significant reduction in anxiety, which persisted over a 1-year follow-up period (Zwier and Rao 1994).

Selective Mutism

The prevalence of selective mutism in children is estimated to be less than 1% (Dow et al. 1995). Selective mutism is characterized by an absence of speech in at least one specific social situation, usually school, despite the child's ability to speak in other situations (American Psychiatric Association

2000). Selective mutism has been viewed as a variant of social anxiety disorder (Black and Uhde 1992).

Selective Serotonin Reuptake Inhibitors

Fluoxetine

Fifteen children and adolescents (ages 6–11 years) with selective mutism were randomly assigned to fluoxetine (dosage range = 12–27 mg/day; mean daily dose = 21.4 mg) or placebo for a 12-week trial (Black and Uhde 1994). Significant improvements on ratings of selective mutism were observed in both fluoxetine-treated and placebo-treated subjects. The group treated with fluoxetine showed significantly more improvement on parent ratings of mutism change and global change than did the group receiving placebo. However, most patients in the study continued to be very symptomatic at study end. Side effects were minimal and not significantly different between the groups.

In a 9-week open trial of fluoxetine (dosage range = 10–60 mg/day; mean daily dose = 28.1 mg) in 21 children (ages 5–14 years) with selective mutism, 76% of patients showed improvement, with decreased anxiety and increased speech in public settings (Dummit et al. 1996).

In case reports of a 4-year-old girl (Wright et al. 1995) and a 12-year-old girl (Black and Uhde 1992) with selective mutism, fluoxetine treatment resulted in clinically significant improvement of symptoms.

Fluvoxamine

A 6-year-old girl was reported to have resolution of symptoms of selective mutism when treated with fluvoxamine (100 mg/day) (Lafferty and Constantino 1998).

Monoamine Oxidase Inhibitors

Phenelzine

Case studies of five children treated with phenelzine (30–60 mg/day) reported positive response (Golwyn and Sevlie 1999; Golwyn and Weinstock 1990). Weight gain was the most common side effect.

Separation Anxiety Disorder

The prevalence of separation anxiety in children is estimated to be 3.5% (J. C. Anderson et al. 1987). Children with separation anxiety disorder have excessive anxiety and worry about separation from home or from a person to whom they are attached (American Psychiatric Association 2000). School refusal or school phobia may be a symptom of separation anxiety disorder. A long-term follow-up of children with school phobia found that in adulthood, these individuals lived with their parents more often, had fewer children, and more psychiatric consultation than did a general population comparison group (Flakierska-Praquin et al. 1997).

Tricyclic Antidepressants

Imipramine

Imipramine has been the most studied medication for the treatment of separation anxiety disorder, and the treatment results have been mixed. In a 6-week double-blind, placebo-controlled trial, 35 children with school phobia were randomly assigned to imipramine (dosage range = 100–200 mg/day; mean daily dose = 152 mg) or placebo (Gittelman-Klein and Klein 1971). All children received concurrent behavioral treatment. Imipramine treatment was significantly superior to placebo in rates of school return (81% and 47%, respectively). However, in another controlled study of

imipramine for separation anxiety disorder (Klein et al. 1992), no significant superiority was found for imipramine (dosage range = 75–275 mg/day; mean daily dose = 153 mg), compared with placebo, in reduction of anxiety symptoms. The most frequent imipramine side effect was irritability or angry outbursts.

Imipramine was compared with alprazolam in an 8-week controlled study in which 24 children and adolescents (ages 7–17 years) with school refusal were randomly assigned to imipramine (dosage range = 150–200 mg/day; mean daily dose = 164.3 mg), alprazolam (dosage range = 1–3 mg/day; mean daily dose = 1.8 mg), or placebo (Bernstein et al. 1990). There was a significant reduction in anxiety ratings from baseline to endpoint in both groups treated with medication, compared with the group receiving placebo. Side effects were mild, with abdominal pain, headaches, and drowsiness the most commonly reported.

The efficacy of imipramine versus placebo in combination with CBT was assessed in the treatment of school refusal in adolescents (Bernstein et al. 2000). Sixty-three adolescents with school refusal were randomly assigned to either imipramine (mean daily dose = 182 mg) plus CBT or placebo plus CBT for an 8-week trial. The group treated with imipramine plus CBT showed a significantly higher rate of school attendance than did the group treated with placebo plus CBT (70% vs. 28%, respectively). In a 1-year follow-up of 41 of the 63 subjects, no significant differences between the two groups were found in prevalence of anxiety diagnoses (Bernstein et al. 2001).

Clomipramine

A 12-week double-blind, placebo-controlled trial of clomipramine (dosage range = 40–75 mg/day) in 46 children and adolescents with school refusal failed to show a significant positive effect (Berney et al. 1981).

Benzodiazepines

Graae et al. (1994) conducted a double-blind crossover trial of 4 weeks of clonazepam therapy (dosage range = 0.5–2.0 mg/day) and 4 weeks of placebo in 15 children (ages 7–13 years) with anxiety disorders, predominantly separation anxiety disorder. No significant improvement was found relative to baseline for clonazepam or placebo. Two boys discontinued the study because of significant disinhibition and marked irritability, aggression, and tantrums, and 1 boy was noncompliant with the protocol. The most common clonazepam side effects were drowsiness, irritability, and oppositional behavior.

In an open-label study, 9 children (ages 8–11 years) with school refusal received chlordiazepoxide (10–30 mg daily) for 5–30 days (D'Amato 1962). Eight of the children (89%) regularly attended school after 2 weeks of treatment. Drowsiness was the only reported side effect.

Gabapentin

Two adolescents with school refusal who received gabapentin (dosage range = 1,200–2,000 mg/day) were reported to have a positive response to treatment (Durkin 2002).

Posttraumatic Stress Disorder

The prevalence of PTSD in adolescents is reported to be 6.3% (Giaconia et al. 1995). The criteria for diagnosing PTSD in youths are the same as those used for adults (American Psychiatric Association 2000). PTSD symptoms in children tend to vary over time, and although the disorder is chronic, the course is prolonged with greater severity of the stressor (Clarke et al. 1993).

Citalopram

Eight adolescents with PTSD received citalopram in a fixed daily dose of 20 mg in a 12-week open-label study (Seedat et al. 2001). Core PTSD symptoms of reexperiencing, avoidance, and

hyperarousal showed statistically significant improvement at week 12, with a 38% reduction in total score on the Clinician-Administered PTSD Scale—Child and Adolescent Version (CAPS-CA; Nader et al. 1996). Citalopram was well tolerated, and the most common side effects were increased sweating, nausea, headache, and tiredness.

In a larger 8-week open trial, Seedat et al. (2002) treated 24 children and adolescents with citalopram (dosage range = 20–40 mg/day; mean daily dose 20 mg). Both the children and adolescents had a significant reduction in CAPS-CA scores at endpoint. Common side effects of citalopram were drowsiness, headache, nausea, and increased sweating.

Clonidine

Seven preschool children (ages 3–6 years) with a diagnosis of PTSD received open treatment with clonidine at a dosage range of 0.05–0.15 mg/day (Harmon and Riggs 1996). To decrease sedation, oral clonidine was subsequently converted to a clonidine patch. The majority of children showed at least moderate improvements in hyperarousal, hypervigilance, insomnia, nightmares, and mood lability.

Guanfacine

A 7-year-old girl with PTSD received guanfacine 0.5 mg daily, which suppressed PTSD nightmares for the 7-week period of administration (Horrigan 1996).

Carbamazepine

Twenty-eight children and adolescents (ages 8–17 years) with a diagnosis of PTSD received carbamazepine (dosage range = 300–1,200 mg/day) for an average of 35 days. Twenty-two patients (78%) became asymptomatic, and the remaining six patients were significantly improved during the course of treatment (Looff et al. 1995).

Propranolol

Eleven children (ages 6–12 years) with a diagnosis of PTSD participated in an off–on–off medication design of 4 weeks of propranolol treatment (Famularo et al. 1988). Propranolol was initiated at 0.8 mg/kg/day and titrated to a maximum of 2.5 mg/kg/day. A significant improvement in PTSD symptoms was found during the treatment period. Side effects included sedation and mildly lowered blood pressure and pulse.

Panic Disorder

The prevalence of panic disorder in children and adolescents ranges from 0.6% to 5.0% in the community and from 0.2% to 9.6% in clinical settings (Masi et al. 2001). The diagnostic criteria for panic disorder in children and adolescents are the same as those for adults (American Psychiatric Association 2000). Panic disorder in youths is a chronic condition, and there is continuity between pediatric and adult panic disorder (Biederman et al. 1997).

Selective Serotonin Reuptake Inhibitors

In an open-label trial, 12 children and adolescents (ages 7–17 years) with panic disorder were treated with an SSRI for 6–8 weeks (Renaud et al. 1999). Mean daily doses of SSRIs were fluoxetine 34 mg, paroxetine 20 mg, and sertraline 125 mg. Adjunctive benzodiazepines were used for 8 patients. Seventy-five percent of patients showed much to very much clinical improvement while receiving treatment with SSRIs. At the end of the trial, 8 patients (67%) no longer fulfilled panic disorder criteria. No significant side effects were found.

Paroxetine

A chart review was conducted of 18 child and adolescent outpatients (ages 7–16 years) with a

diagnosis of panic disorder who received monotherapy with paroxetine (dosage range = 10–40 mg/day; mean daily dose = 23 mg) (Masi et al. 2001). The mean paroxetine treatment duration was 11.7 months. Fifteen patients (83%) had a CGI score of much or very much improved. The most common side effects were nausea, tension–agitation, sedation, insomnia, palpitations, and headache.

Citalopram

Three youths (ages 9, 13, and 16 years) with panic disorder and school phobia were treated with citalopram (up to 20 mg/day) over an 8- to 15-month period. All patients experienced resolution of panic attacks during the course of citalopram treatment (Lepola et al. 1996).

Tricyclic Antidepressants

An 11-year-old girl with panic disorder and agoraphobia was treated with imipramine (75 mg/day), which resulted in cessation of panic attacks (Ballenger et al. 1989). A 9 year-old boy with panic disorder and Tourette's syndrome was treated with imipramine (25 mg daily). Within 1 week of treatment onset, the boy's panic episodes ceased, and the cessation was maintained over a 2-year period (Sverd 1988).

Two cases of children (ages 8 and 13 years) with panic disorder and agoraphobia were reported in which the combination of imipramine and alprazolam resulted in complete remission of symptoms (see Ballenger et al. 1989).

Benzodiazepines

In a 2-week open trial, four adolescents with panic disorder were treated with clonazepam (0.5 mg twice daily). A significant reduction in panic attacks (from 3 attacks per week to 0.25 per week) was reported (Kutcher and MacKenzie 1988).

Mixed Anxiety Disorders

Selective Serotonin Reuptake Inhibitors

Fluvoxamine

One hundred twenty-eight outpatient children and adolescents (ages 6–17 years) with GAD, social anxiety disorder, or separation anxiety disorder (who had received 3 weeks of open treatment with supportive psychoeducational therapy without improvement) were randomly assigned to fluvoxamine (up to 300 mg) or placebo for an 8-week trial (Research Units on Pediatric Psychopharmacology Anxiety Study Group 2001). The group treated with fluvoxamine had a significantly greater reduction in scores on the Pediatric Anxiety Rating Scale (Research Units on Pediatric Psychopharmacology Anxiety Study Group 2002a) than did the group treated with placebo. On the CGI-I scale, the response rate was 76% in the group treated with fluvoxamine and 29% in the group receiving placebo. Adverse effects of abdominal discomfort and increased motor activity were more common in the group treated with fluvoxamine than in the group treated with placebo. Following completion of the 8-week placebo-controlled study, the 128 patients entered a 6-month open-label treatment phase (Research Units on Pediatric Psychopharmacology Anxiety Study Group 2002b). Anxiety symptoms remained low in 33 of 35 (94%) subjects who initially responded to fluvoxamine. Of 14 fluvoxamine nonresponders switched to fluoxetine, anxiety symptoms significantly improved in 10 (71%) patients. Among 48 placebo nonresponders, 27 (56%) showed significant improvement in anxiety on fluvoxamine.

Fluoxetine

Seventy-four youths (ages 7–17 years) with GAD, separation anxiety disorder, and/or social phobia were randomly assigned to fluoxetine (20 mg/day) or to placebo for 12 weeks (Birmaher et al. 2003). Sixty-one percent of fluoxetine-treated patients and 35% of placebo-treated patients were much or

very much improved. Fluoxetine was well tolerated, with mild headache and gastrointestinal symptoms reported as adverse events.

Fluoxetine's efficacy in long-term treatment of children with GAD, separation anxiety disorder, and/or social phobia was assessed in a 1-year open treatment (Clark et al. 2005) following the acute-phase study (Birmaher et al. 2003). Compared with youths taking no medication, those taking fluoxetine (*n* = 42) showed significantly superior outcome in anxiety measures. These investigators concluded that fluoxetine is effective in maintenance treatment of anxiety disorders in youth.

Clinical Recommendations for Anxiety Disorders

SSRIs are the medication treatment of choice for OCD in children and adolescents (Riddle 1998). Clomipramine is also effective in the treatment of this disorder; however, anticholinergic side effects often make this a less tolerable agent than SSRIs. A 10- to 12-week trial at adequate dosages is required to determine whether a child with OCD will respond to an SSRI (Greist et al. 1995). If a child fails to respond to one SSRI, switching to another SSRI is a reasonable strategy. Clomipramine may be a third treatment option, either as monotherapy or as augmentation of an SSRI. Other possible SSRI augmentation strategies are clonazepam, antipsychotics, lithium, and buspirone; however, these agents have not received systematic study in children (American Academy of Child and Adolescent Psychiatry 1998). Some children may require long-term medication maintenance; however, it is reasonable to attempt medication discontinuation 1 year after symptom resolution. Medication should be tapered gradually to assess for relapse and to avoid discontinuation symptoms (Grados et al. 1999).

In regard to other childhood anxiety disorders, SSRIs are first-line treatment (Reinblatt and Walkup 2005). Venlafaxine has also demonstrated efficacy for the treatment of childhood GAD. Other treatment options include buspirone, TCAs, and benzodiazepines (Bernstein et al. 1996). However, benzodiazepines should be used only on a short-term basis (i.e., weeks) because of the potential for abuse and dependence in youths (Riddle et al. 1999).

ATTENTION-DEFICIT/HYPERACTIVITY DISORDER

The prevalence of ADHD in children and adolescents is estimated to range from 5% to 12% (Barbaresi et al. 2002; Centers for Disease Control and Prevention 2005; Rowland et al. 2002), although only about half of children diagnosed with ADHD receive treatment (Centers for Disease Control and Prevention 2005). In addition to the core behavioral features of inattention, hyperactivity, and impulsivity, children with ADHD often have significant impairment in social and academic functioning (Barkley 2005). About 4% of adults in the general population meet criteria for ADHD (Kessler et al. 2006). Of all of the childhood psychiatric disorders, ADHD has the greatest number of pharmacological treatment studies.

Psychostimulants

The classes of psychostimulants include methylphenidate, dexmethylphenidate, dextroamphetamine, mixed amphetamine salts, and L-lysine-D-amphetamine (lisdexamfetamine). By the 1980s, there were already hundreds of randomized, controlled trials showing the efficacy of stimulants for the treatment of ADHD in school-age children (Greenhill et al. 1999). Beginning in the late 1980s and 1990s, the intensive study of the pharmacokinetics and pharmacodynamics of stimulant medications was undertaken, pioneered by the group at the University of California at Irvine. Analog classroom settings were used to examine the hour-by-hour effects of stimulant medications on behavior and cognition and its relationship to serum stimulant medications. Such studies led to the development of methylphenidate (Swanson et al. 1998, 1999, 2000, 2002, 2003), mixed salts of amphetamine–dextroamphetamine (Greenhill et al. 2003; McCracken et al. 2003), extended-release methylphenidate (Swanson et al. 2004; Wigal et al. 2003), dexmethylphenidate hydrochloride (Quinn et al. 2004), and

lisdexamfetamine dimesylate (Findling et al. 2006a).

Subsequently, numerous large-scale clinical trials proved the efficacy of these new agents (Biederman et al. 2002; Greenhill et al. 2002, 2005; McCracken et al. 2003; Pelham et al. 1999; Wigal et al. 2005a; Wolraich 2000; Wolraich et al. 2001). A methylphenidate transdermal patch (Findling and Lopez 2005; Pelham et al. 2005) has been recently approved for use in the treatment of ADHD. In the study of the transdermal patch, 270 children with ADHD were randomly assigned to receive either a placebo patch or varying dosages of the methylphenidate patch in a double-blind design. At the end of the 5-week study, 72% of those on the active patch were classified as responders compared to 24% on placebo; side effects were similar to oral methylphenidate (decreased appetite, insomnia, weight loss, tics).

Lisdexamfetamine dimesylate is a "prodrug" in which D-amphetamine is covalently bound to L-lysine (Findling et al. 2006a). In the bloodstream, the lysine is hydrolyzed to yield the active stimulant. The prodrug appears to have lower potential than amphetamine for oral or intravenous abuse (Jasinski and Krishman 2006a, 2006b). In the pivotal trials, 290 children (ages 6–12 years) with ADHD were randomly assigned to either placebo (n = 72) or different dosages of lisdexamfetamine dimesylate (30, 50, 70 mg/day). All doses of lisdexamfetamine dimesylate were superior to placebo (P <0.0001) throughout the 4-week trial at three different time points during the day (10 A.M., 2 P.M., and 6 P.M.). Common side effects of lisdexamfetamine dimesylate were decreased appetite (39%), irritability (10%), insomnia (19%), nausea/vomiting (6%–9%), and weight loss (9%). No serious adverse events were reported. The medication was well tolerated in long-term follow-up, with no significant laboratory or ECG abnormalities reported (Childress et al. 2006).

Initial research with long-acting stimulants was carried out in school-age children, but recent controlled trials of stimulants have focused on adolescents (T. J. Spencer et al. 2006b; Wilens et al. 2006b) and adults (Biederman et al. 2006a; Weisler et al. 2006). These studies in older individuals show response rates to stimulants similar to those of children; with adequate response for most subjects being obtained with 70–100 mg of methylphenidate or 40–60 mg of amphetamine a day.

Preschoolers with ADHD have also been the focus of recent work. In the NIMH Preschool ADHD Treatment Study (PATS), 183 children (ages 3–5 years) underwent an open-label trial of methylphenidate; subsequently 165 of these subjects were randomized into a double-blind, placebo-controlled crossover trial of methylphenidate lasting 6 weeks (Greenhill et al. 2006b). One hundred forty subjects who completed this second phase went on to enter a long-term maintenance study of methylphenidate. Parents of subjects in this study were required to complete a 10-week course of parent training before their child was treated with medication. Of note, only 37 of 279 enrolled parents felt that the behavior training resulted in significant or satisfactory improvement (Greenhill et al. 2004).

Results from the short-term, open-label run-in and double-blind crossover studies do show that methylphenidate is effective in preschoolers with ADHD (Wigal et al. 2006). The mean optimal dose of methylphenidate was found to be 0.7 + 0.4 mg/kg/day, which is lower than the mean of 1.0 mg/kg/day found to be optimal in the Multimodal Treatment of ADHD (MTA) study with school-age children. Eleven percent of subjects discontinued methylphenidate because of adverse events (Wigal et al. 2006). Also relative to the MTA study, the preschool group showed a higher rate of emotional adverse events, including crabbiness, irritability, and proneness to crying. The conclusion was that the dose of methylphenidate (or any stimulant) should be titrated more conservatively in preschoolers than in school-age patients, and lower mean doses may be effective. A pharmacokinetic study done as part of the PATS protocol showed that preschoolers metabolized methylphenidate more slowly than did school-age children, perhaps explaining these results (McGough et al. 2006).

Longer-term open-label studies of these agents, often lasting up to 2 years (McGough et al. 2005; Wilens et al. 2003b, 2005), have also been performed, giving the field more data about efficacy and

safety after prolonged use. These studies do not show the presence of any major medical adverse events, with no abnormalities of hematological or chemical measures (Biederman et al. 2002; Greenhill et al. 2002; McCracken et al. 2003; Wolraich 2000; Wolraich et al. 2001).

Atomoxetine

Atomoxetine is a noradrenergic reuptake inhibitor that has indirect effects on dopamine reuptake in cortex but not in the striatum (Bymaster et al. 2002). Numerous double-blind, placebo-controlled trials have demonstrated its efficacy in the treatment of ADHD in children, adolescents, and adults (Michelson et al. 2001, 2002, 2003). Given its pharmacokinetic half-life of 5 hours, it is generally dosed twice a day. While open trials comparing methylphenidate to atomoxetine showed the two agents to have similar efficacy (Kratochvil et al. 2002), double-blind, placebo-controlled trials comparing atomoxetine to amphetamine (Biederman et al. 2006b; Wigal et al. 2005b) and methylphenidate (Michelson 2004) have shown the stimulants to be more efficacious.

Atomoxetine is effective in treating ADHD in those with comorbid tics and may also reduce tics (Allen et al. 2005). It is also useful in children with ADHD who have comorbid anxiety, showing effectiveness in treating anxiety and inattention (Sumner et al. 2005). Atomoxetine is well tolerated in long-term use. In a global multicenter study, 416 children and adolescents who responded to an initial 12-week open-label period of treatment with atomoxetine were randomly assigned to continued atomoxetine treatment or placebo for 9 months under double-blind conditions. Atomoxetine was significantly superior to placebo in preventing relapse (defined as a return to 90% of baseline symptom severity), 22.3% and 37.9%, respectively (Michelson 2004). Data from 13 atomoxetine studies (6 double-blind, 7 open-label) were pooled for subjects ages 12–18 years with ADHD (Wilens et al. 2006b). Of the 601 atomoxetine-treated subjects in this meta-analysis, 537 (89.4%) completed 3 months of acute treatment. At the time of publication, a total of 259 subjects (48.4%) were continuing atomoxetine treatment; 219 of these subjects had completed at least 2 years of treatment. Symptoms remained improved up to 24 months without dosage escalation. During the 2-year treatment period, 99 (16.5%) subjects discontinued treatment due to lack of effectiveness, and 31 (5.2%) subjects discontinued treatment due to adverse events. No clinically significant abnormalities in height, weight, blood pressure, pulse, mean laboratory values, or ECG parameters were found.

Tricyclic Antidepressants

Before the advent of atomoxetine, TCAs were the primary alternative to stimulant treatment of ADHD. There have been 15 double-blind, placebo-controlled studies of TCAs demonstrating the efficacy of desipramine, imipramine, amitriptyline, nortriptyline, and clomipramine in the treatment of children with ADHD (Daly and Wilens 1998; Popper 2000; Prince et al. 2000). Desipramine is rarely used today because of isolated reports in the 1990s of sudden death at therapeutic dosages (Popper and Ziminitzky 1995). In general, there has been a decline in the use of TCAs for the treatment of ADHD due to the need to monitor ECG (see Appendix) and the risk of death in the event of overdose.

Bupropion

Bupropion is an antidepressant with noradrenergic and dopaminergic actions. Simeon et al. (1986) conducted a 14-week single-blind study consisting of placebo baseline for 4 weeks, bupropion (dosage range = 50–150 mg; mean daily dose = 135 mg) for 8 weeks, and placebo posttreatment for 2 weeks. Seventeen boys with ADHD and conduct disorder (ages 7–13 years) participated in the study. Significant improvement in hyperactivity, conduct problems, and global functioning was found.

A double-blind, placebo-controlled four-center study was conducted to assess the efficacy of bupropion in the treatment of childhood ADHD (Conners et al. 1996). One hundred nine children (ages 6–12 years) with ADHD were randomly assigned to bupropion (n = 72) or placebo (n = 37) for a 6-week trial. Dosages of bupropion ranged from 3 to 6 mg/kg/day. Significant treatment effects were

found for hyperactivity, impulsivity, conduct problems, and attention. Moderate effect sizes of bupropion that were somewhat less than those for stimulant treatment of ADHD were found. The most frequent adverse effects with bupropion were rash, urticaria, nausea, and vomiting. Although no patients experienced a seizure, 6 of 72 children who received bupropion had electroencephalograms (EEGs) that changed from normal at baseline to abnormal on the final day of treatment (approximately 4 weeks later) (Conners et al. 1996).

Bupropion was compared with methylphenidate in a small double-blind crossover study (Barrickman et al. 1995). Fifteen children and adolescents (ages 7–17 years) were randomly assigned to bupropion or methylphenidate for 6 weeks, underwent washout for 2 weeks, and were crossed over to the other medication. The dosage range of bupropion was 1.4–5.7 mg/kg/day (mean daily dose = 3.3 mg/kg) and the dosage range of methylphenidate was 0.4–1.3 mg/kg/day (mean daily dose = 0.7 mg/kg). Bupropion and methylphenidate produced significant and similar improvement in ADHD symptoms. Despite this finding, however, the two medications have never been compared in more rigorous parallel-group designs, and clinical experience strongly suggests that the effect size for bupropion is not as great as that for stimulants.

Clonidine

A review of the literature from 1980 to 1999 found 39 studies regarding the use of clonidine for symptoms of childhood ADHD, and 11 of the studies (*n* = 150) had sufficient data to be included in a meta-analysis (Connor et al. 1999). Of these 150 subjects, 42 received clonidine for ADHD, and the others received clonidine for ADHD comorbid with tic disorders (*n* = 67), developmental disorders (*n* = 15), or conduct disorders (*n* = 26). The mean daily dose of clonidine was 0.18 mg, and the average length of treatment was 10.9 weeks. Clonidine showed a moderate effect size of 0.58 on symptoms of ADHD, which is smaller than the effect size (0.82) reported for stimulant treatment of ADHD (Swanson et al. 1995).

Guanfacine

Two open trials and one controlled trial provide some support for the use of guanfacine in the treatment of youths with ADHD. In a study by Hunt et al. (1995), 13 children and adolescents with ADHD received guanfacine (mean daily dose = 3.2 mg) for 1 month. Significant improvements in hyperactivity and inattention were found. In another study by Chappell et al. (1995b), 10 children and adolescents with comorbid ADHD and Tourette's syndrome received guanfacine (mean daily dose = 1.5 mg) over a 4- to 20-week period. Four of the 10 children (40%) had moderate to marked improvement in ADHD symptoms.

In an 8-week double-blind, placebo-controlled trial, 34 children and adolescents (ages 7–14 years) with ADHD and tic disorder were randomly assigned to guanfacine (dosage range = 1.5–3.0 mg/day) or placebo (Scahill et al. 2001). There was a 37% improvement in ADHD symptoms for children treated with guanfacine, compared with an 8% improvement in ADHD symptoms for children receiving placebo. The most common side effects of guanfacine were sedation and dry mouth. There were no significant changes in pulse or blood pressure with guanfacine.

An extended-release formulation of guanfacine has been recently studied in a double-blind, placebo-controlled Phase III multicenter trial (Melmed et al. 2006). Children and adolescents ages 6–17 years were randomly assigned to placebo or 2, 3, or 4 mg/day of guanfacine. All three doses of guanfacine were superior to placebo in reducing symptoms of ADHD. The most commonly reported side effects were headache, somnolence, and fatigue. No serious adverse events were reported. In healthy young adults (ages 19–24 years), abrupt discontinuation of 4 mg of extended-release guanfacine did not lead to increases in blood pressure or ECG abnormalities (Kisicki et al. 2006).

Modafinil

Modafinil, a nonstimulant activator of the cortex approved for the treatment of narcolepsy, was studied to determine its efficacy in the treatment of ADHD. A 9-week double-blind, placebo-controlled trial randomly assigned 248 subjects to either placebo or modafinil (dosage range = 170–425 mg once per day) (Biederman et al. 2005d). At study termination, 48% of subjects on modafinil were rated as much or very much improved compared to 17% of those on placebo (effect size vs. placebo = 0.69). The most common adverse events reported were insomnia (29%), headache (20%), and decreased appetite (16%). In a second controlled trial, 200 subjects were randomly assigned to placebo or modafinil (Greenhill et al. 2006a); 52% of those on modafinil were classified as responders versus 18% of subjects on placebo ($P < 0.001$). A double-blind, placebo-controlled discontinuation study involving 189 patients with ADHD also demonstrated efficacy of modafinil in ADHD (Swanson et al. 2006b). While the medication was well tolerated by most subjects in open-label follow-up studies, one case of suspected Stevens-Johnson syndrome was reported, and the FDA declined to approve the medication for clinical use (U.S. Food and Drug Administration 2006c). Given the low response rate (~50%) relative to that seen with stimulants (65%–85%), it is not likely that modafinil would have emerged as a first-line treatment for ADHD. Clinicians face a dilemma if they choose to use modafinil (Provigil) off label for the treatment of ADHD; this should be attempted only if all other agents have failed and the patient and family are informed of the reason for the FDA's failure to approve the medication.

Other Antidepressants

Fenfluramine, a potent serotonergic agonist, was found to be ineffective in the treatment of ADHD (Donnelly et al. 1989). Thus, findings from open trials suggesting improvement in ADHD symptoms with SSRI treatment (Barrickman et al. 1991; Gammon and Brown 1993) must be greeted with skepticism. In the Gammon and Brown (1993) study, improvement in mood and attention was seen when fluoxetine was added to methylphenidate when the clinical response after monotherapy with the stimulant was deemed insufficient in a sample of 32 children and adolescents with ADHD. However, in a later open-label study of sertraline or fluoxetine in the treatment of seven children and adolescents with ADHD and major depression, Findling (1996) found no improvement in ADHD symptoms for any patient treated with SSRIs. More recently, the addition of fluvoxamine to methylphenidate was not demonstrated to be effective relative to addition of placebo in a sample of children with ADHD and comorbid anxiety (Abikoff et al. 2005).

In an open trial of venlafaxine, 7 of 16 children and adolescents (44%) showed some improvement in ADHD symptoms of hyperactivity and impulsivity; however, no improvement was seen in cognitive symptoms (Olvera et al. 1996). The mean daily dose of venlafaxine was 60 mg. Four patients (25%) were unable to tolerate the medication, with 3 of the patients discontinuing medication because of worsening hyperactivity. Other side effects included drowsiness, irritability, and nausea. No effects on blood pressure or heart rate were found. No double-blind, placebo-controlled trials have ever proven the efficacy of venlafaxine in the treatment of ADHD. Given concerns about antidepressants increasing the risk of suicidal ideation, anti-depressants without proven efficacy in the treatment of ADHD should not be used in its treatment. They may be used in conjunction with an established medication treatment for ADHD to treat a comorbid anxiety or depressive disorder.

Clinical Recommendations for Attention-Deficit/Hyperactivity Disorder

Recently, the Texas Children's Medication Algorithm Project (CMAP) has revised the algorithm for the treatment of ADHD (Pliszka et al. 2006a). Based on current research and panel discussion, the stages of medication treatment were established as follows:

- Stage 1: Psychostimulant
- Stage 2: Alternative psychostimulant
- Stage 3: Atomoxetine

- Stage 3a: Combination of stimulant and low-dose atomoxetine
- Stage 4: Bupropion or TCA
- Stage 5: Alternative antidepressant from stage 5
- Stage 6: Alpha agonist (guanfacine or clonidine)

Arnold (2000) reviewed studies in which subjects underwent a trial of both amphetamine and methylphenidate. This review suggested that approximately 41% of subjects with ADHD responded equally to both methylphenidate and amphetamine, while 44% responded preferentially to one of the classes of stimulants. This suggests the initial response rate to stimulants may be as high as 85% if both stimulants are tried (in contrast to the finding of 65%–75% response when only one stimulant is tried). There is at present, however, no method to predict which stimulant will produce the best response in a given patient. The recent practice parameters of the American Academy of Child and Adolescent Psychiatry (2007) characterize all FDA-approved agents (stimulants and atomoxetine) as appropriate for initial treatment of ADHD, with antidepressants and alpha agonists as second line.

DISRUPTIVE BEHAVIOR DISORDERS AND AGGRESSION

Oppositional Defiant Disorder and Conduct Disorder

Oppositional defiant disorder (ODD) is a pattern of negativistic, defiant, angry behavior that is persistent and causes impairment in the child's social functioning. Conduct disorder (CD) consists of antisocial and aggressive behavior (lying, stealing, fighting, fire setting, destruction of property, truancy, running away) (American Psychiatric Association 2000). ODD and CD are highly comorbid with ADHD, particularly in younger children (Maughan et al. 2004; Pliszka et al. 1999).

Psychostimulants

The efficacy of methylphenidate in treating 84 youths (ages 6–15 years) with CD, with and without ADHD, was assessed in a 5-week double-blind, placebo-controlled trial. Ratings of antisocial behaviors specific to CD were significantly reduced by methylphenidate treatment (up to 60 mg/day) (Klein et al. 1997). The severity of the ADHD did not affect the response of CD symptoms to the stimulant studies. Since this study, multiple double-blind, placebo-controlled trials have shown that ODD responds to stimulant medication, yielding an effect size similar to that for the ADHD symptoms (American Psychiatric Association 2000; Pelham et al. 2001; T. J. Spencer et al. 2006a).

Atomoxetine

Children and adolescents (ages 8–18 years) with ADHD were treated for approximately 8 weeks with placebo or atomoxetine under randomized, double-blind conditions. Of the 293 subjects, 39% were diagnosed with comorbid ODD and 61% were not (Newcorn et al. 2005). Treatment group differences and differences between patients with and without comorbid ODD were examined post hoc for changes on numerous clinical measures. Youths with ADHD and comorbid ODD showed statistically significant improvement in ADHD and ODD symptoms as well as in quality-of-life measures on atomoxetine relative to placebo. Treatment response was similar in youths with and without ODD, although the comorbid group may require higher doses to achieve response than those with ADHD alone.

In general, a child with ODD or CD should be treated with a stimulant or atomoxetine before proceeding to the use of other psychotropic agents. The use of more potent agents (mood stabilizers, antipsychotics) is generally reserved for those with severe aggression, and then only after a behavioral treatment has failed (Pappadopulos et al. 2003; Pliszka et al. 2006a).

Aggressive Behavior

While ODD and CD are *syndromes,* aggression is a *symptom.* Although many children and adolescents with CD are aggressive, a child can meet criteria for CD without being aggressive; aggression may

present as a problematic symptom in children with depression, psychosis or bipolar disorder without the child meeting criteria for CD. Thus, the clinician must be clear whether ODD/CD or aggression is the target of treatment, as studies have addressed the problems separately. Treatments for ADHD have been used to target ODD/CD, whereas mood stabilizers and antipsychotics have been used in patients with severe aggressive outbursts, regardless of diagnosis (Pappadopulos et al. 2006).

Psychostimulants

In a meta-analysis of the literature from 1970 to 2001 that utilized 28 studies to determine the effect size for stimulants on overt and covert aggression-related behaviors in children with ADHD, it was found that the mean effect size for aggressive behaviors was similar to that for core behaviors of ADHD (Connor et al. 2002; Pappadopulos et al. 2006).

Risperidone

A significant body of research has accumulated showing the effectiveness of risperidone in the treatment of aggression, although most of these studies involve patients with subaverage intelligence (Pappadopulos et al. 2006). One hundred ten children (ages 5–12 years) with an IQ of 36–84 with a disruptive behavior disorder were enrolled in a clinical trial of risperidone consisting of a 1-week single-blind, placebo run-in period followed by a 6-week double-blind, placebo-controlled period (Snyder et al. 2002). Eighty percent of subjects had comorbid ADHD. Risperidone dosages ranged from 0.02 to 0.06 mg/kg/day. The risperidone-treated subjects showed a significant ($P < 0.001$) reduction (47.3%) in mean scores versus placebo-treated subjects (20.9%) on the Conduct Problem subscale of the Nisonger Child Behavior Rating Form (NCBRF) ($P < 0.001$). The effect of risperidone was unaffected by diagnosis, presence/absence of ADHD, psychostimulant use, and IQ status. Risperidone produced no changes on the cognitive variables, and the most common side effects were somnolence, headache, appetite increase, and dyspepsia. Somnolence did not predict response of aggressive symptoms. Side effects related to extrapyramidal symptoms were reported in 7 (13.2%) and 3 (5.3%) of the subjects in the risperidone and placebo groups, respectively ($P = 0.245$).

Other double-blind, placebo-controlled trials of risperidone in children and adolescents with disruptive behavior disorders (and subaverage IQ) have yielded similar results, with no negative trials reported (Aman et al. 2002; Buitelaar et al. 2001; LeBlanc et al. 2005). Weight gain was a significant side effect in these studies, but there has not been evidence of adverse neuropsychological effects (Gunther et al. 2006). Addition of stimulant does not appear to increase rates of side effects and enhances treatment of hyperactivity (Aman et al. 2004). Indeed adding risperidone to a stimulant to control aggression has become a common practice, although a recent controlled study showed that aggression was equally reduced when either placebo or risperidone was added to psychostimulant medication (Armenteros et al. 2007). The sample in this study was small ($N = 25$), but the study should caution clinicians that aggression can respond to psychosocial events, like the expectations of a study.

Because of weight gain and increased prolactin associated with risperidone, concern exists regarding its long-term use (Correll and Carlson 2006). The long-term safety and efficacy of risperidone in disruptive behavior disorders in children with subaverage IQ were studied in a 48-week open-label extension study of risperidone in 77 children (Turgay et al. 2002). Subjects received risperidone at daily doses of between 0.02 and 0.06 mg/kg. Adverse events were reported for 76 participants; none were serious, and most were mild/moderate in severity. Somnolence (52%), headache (38%), and weight gain (36%) were the most common adverse events. The degree of sedation was mild and not associated with cognitive deterioration. Mean weight gain was 8.5 kg, half of this attributable to normal growth. Asymptomatic peak prolactin levels were observed within 4 weeks of beginning risperidone treatment and declined over time to within normal range. At study endpoint, mean prolactin levels were statistically significantly greater than baseline only in male participants but

within the normal range. Twenty participants experienced mild or moderate extrapyramidal symptoms, but these did not cause withdrawal from the study.

The pooled database of five studies of the long-term use of risperidone (*n* = 700) included 700 children ages 5–15 years who had received risperidone for 11 or 12 months (Dunbar et al. 2004). Subjects also had baseline and 11- or 12-month height measurements (*n* = 350); girls ≥9 years and boys ≥10 years also had baseline and 11- or 12-month Tanner staging (*n* = 222). Risperidone-treated children had a mean increase in height 1.2 cm greater than the reference population, and they experienced no delay in progression through Tanner staging. Transient increases in prolactin did not correlate with growth or sexual maturation. The authors concluded that there was no evidence of statistically or clinically significant growth failure or delay in pubertal onset or progression in children treated for up to 1 year with risperidone.

A full review of all studies of risperidone in the treatment of childhood aggression was recently published (Pandina et al. 2006). This review pooled adverse-event data from these studies (*n* = 688), showing the most common side effects of risperidone to be somnolence (33%), weight gain (20%), hyperprolactinemia (10.2%), and fatigue (10%). In the pooled studies, there was an excess mean weight gain (over normal growth) of 6.0 + 7 kg after 35–43 weeks of treatment. Of the 688 patients, 651 were free of dyskinetic movements at baseline, and only 1 patient developed new dyskinetic movements during the follow-up period (these symptoms resolved even though risperidone was continued). There was no worsening of dyskinetic movements in those with such preexisting symptoms. Rates of extrapyramidal side effects were low throughout the long-term follow-up period. It should be noted that the dosages of risperidone used in these studies were quite low (1–2 mg/day); thus, these results may not apply to dosages in the 6 mg/day range.

Quetiapine

Quetiapine has been studied in an open trial with aggressive children with CD (Findling et al. 2006b) The 8-week trial enrolled 17 children ages 6–12 years. Outcome measures included the Rating of Aggression Against People and/or Property Scale (RAAPPS), the NCBRF, and the Conners Parent Rating Scale (CPRS-48). Blood sampling for pharmacokinetic analyses occurred at the end of weeks 2 and 8: the mean dose of quetiapine at week 8 was 4.4 ± 1.1 mg/kg. Significant decreases in baseline scores of the RAAPPS, and in several subscales of the NCBRF and the CPRS, were found by the end of the study ($P < 0.05$). No patients discontinued because of an adverse event or experienced extrapyramidal side effects. These preliminary data suggest that aggressive children with CD may benefit from quetiapine. The pharmacokinetics of quetiapine supports twice-daily dosing in children. Nine of the subjects in this study were subsequently enrolled in a 26-week open-label trial; they were treated with dosages of quetiapine ranging from 75 to 300 mg/day. Aggression remained well controlled, no subject developed extrapyramidal side effects, and 1 subject had a significant weight gain but remained in the study.

The efficacy and tolerability of quetiapine and divalproex for the treatment of impulsivity and reactive aggression were studied in 33 subjects with bipolar disorder and disruptive behavior disorders (Barzman et al. 2006). The subjects were randomly assigned to quetiapine (400–600 mg/day) or divalproex (serum level 80–120 microgram/mL) for 28 days in this double-blinded study. Repeated-measures analysis of variance (ANOVA) demonstrated statistically significant within-treatment-group effects for divalproex (baseline = 20.6, endpoint = 13.3, $P < 0.0001$) and quetiapine (baseline = 18.8, endpoint = 10.8, $P < 0.0001$) for the Positive and Negative Syndrome Scale (PANSS) Excited Component (EC), but there was no significant difference in the rate of improvement in the PANSS EC scores between the two treatment groups; thus, the two agents showed similar efficacy for the treatment of impulsivity and reactive aggression in this study. No double-blind, placebo-controlled trials of quetiapine in the treatment of aggression have been performed.

Other Atypical Antipsychotics

There have only been small open trials and case reports of the use of aripiprazole, olanzapine, and ziprasidone in the treatment of aggression (Hazaray et al. 2004; Khan et al. 2006; Rugino and Janvier 2005; Staller and Staller 2004; Stephens et al. 2004; Valicenti-McDermott and Demb 2006). In most of these studies, children had primary psychiatry diagnoses other than ODD or CD, such as mood disorders or developmental disorders.

Rugino and Janvier (2005) reported on the use of aripiprazole in a mixed sample (*n* = 17) of children with bipolar disorder and developmental disorders. Only 4 of the subjects responded, but coadministration of alpha$_2$ agonists in a large proportion of the sample may have confounded the results. A retrospective chart review of 32 children (ages 5–19 years) with developmental disabilities treated with aripiprazole was conducted (Valicenti-McDermott and Demb 2006). Twenty-four had diagnoses within the autistic spectrum, and 18 had mental retardation. Other disorders included ADHD/disruptive behavior disorders (*n* = 13), mood disorders (*n* = 7), reactive attachment disorder (n = 2), and sleep disorders (*n* = 2). Target symptoms included aggression, hyperactivity, impulsivity, and self-injurious behaviors. The mean daily aripiprazole starting dose was 7.1 ± 0.32 mg (0.17 mg/kg/day), and the mean daily maintenance dose was 10.55 ± 6.9 mg (0.27 mg/kg/day). While improvement in target symptoms was found in 56% of the sample, side effects were reported in 16 (50%), with the most frequent being sleepiness (*n* = 6). Mean body mass index (BMI) rose significantly, and weight gain was more pronounced in children younger than 12 years.

Inpatient children who received intramuscular ziprasidone or olanzapine for emergency treatment of aggression were found to have similar lengths of stay and number of restraints, but those administered ziprasidone required many more injections and were more likely to require coadministration of lorazepam (Khan et al. 2006).

The effects of olanzapine on aggressive behavior and tic severity was examined in 10 subjects (ages 7–13 years) with a primary diagnosis of Tourette's syndrome and a history of aggressive behavior (Stephens et al. 2004). They were treated in a 2-week single-blind placebo run-in followed by an 8-week treatment-phase trial. The starting dose of olanzapine was 1.25–2.5 mg/day and was titrated at biweekly intervals, as tolerated. The mean dosage at the end of the trial was 14.5 mg/day. Olanzapine produced clinically and statistically significant reductions of aggression and tic severity from baseline to trial completion, as measured by the Achenbach Child Behavior Checklist (CBCL) and Yale Global Tic Severity Scale (YGTSS). Weight gain during the treatment period was the most common adverse effect (range = 2–20 lbs; group mean = 12.0 lbs ± 5.71). No other significant adverse effects were observed during the 10-week trial.

Lithium

The efficacy of lithium in the treatment of CD in youths has been demonstrated in three of the four double-blind, placebo-controlled studies reported to date. Haloperidol, lithium, and placebo were compared in a double-blind, randomized trial for 61 hospitalized children with aggression (ages 5–12 years) and CD. The optimal dosages of haloperidol ranged from 1 to 6 mg/day; the optimal dosages of lithium ranged from 500 to 2,000 mg/day. Both haloperidol and lithium were found to be significantly superior to placebo in reducing aggression. However, there were more adverse effects associated with haloperidol than with lithium, including excessive sedation, acute dystonic reaction, and drooling. Stomachache, headache, and tremor were more common with lithium than with haloperidol (Campbell et al. 1984).

In a subsequent study, Campbell et al. (1995) conducted a 6-week double-blind, placebo-controlled trial of lithium treatment for 50 hospitalized children (ages 5–12 years) with aggression and CD. The mean optimal daily dose of lithium was 1,248 mg, and the mean serum level was 1.12 mEq/L. Lithium was significantly superior to placebo in reducing aggression. The most common lithium side effects

were stomachache, nausea, vomiting, headache, tremor, and urinary frequency.

Eighty-six inpatients (ages 10–17 years) with CD were randomly assigned to lithium (mean daily dose = 1,425 mg; mean serum level = 1.07 mmol/L) or placebo in a 4-week double-blind trial. Aggression ratings decreased significantly for the group treated with lithium, compared with the group treated with placebo. More than 50% of patients in the lithium group experienced nausea, vomiting, and urinary frequency (Malone et al. 2000).

Rifkin et al. (1997) found no significant differences between lithium and placebo in aggression ratings in a 2-week double-blind study of 33 inpatients with CD. The short duration of treatment may have accounted for the lack of efficacy, suggesting that a 4- to 6-week trial is necessary to show response. In a clinical series of 17 hospitalized children, approximately 75% showed reduction of aggression when treated with lithium (Vetro et al. 1985).

Divalproex

Twenty outpatient children and adolescents (ages 10–18 years) with CD or ODD were randomly assigned to divalproex (dosage range = 750–1,500 mg/day; mean blood level = 82 μg/mL) or placebo in a 6-week double-blind, placebo-controlled crossover study. Of the 15 patients who completed both phases, 12 patients (80%) had a statistically significant superior response to divalproex. Increased appetite was the only significant side effect (Donovan et al. 2000).

Steiner et al. (2003) randomly assigned 71 adolescents with CD in a residential facility for juvenile offenders to either therapeutic or low doses of divalproex for 7 weeks; both subjects and outcome raters were blind to treatment status. Reduction in aggression severity ($P = 0.02$), improvement in impulse control ($P < 0.05$), and global improvement ($P = 0.0008$) were greater in the group with therapeutic divalproex levels than in the low-dose condition. Serum level and "Immature defenses" (as assessed by the Weinberger Adjustment Inventory) predicted response to divalproex, but psychiatric comorbidity did not (Saxena et al. 2005).

Saxena et al. (2006) conducted a 12-week open trial of divalproex in 24 children of bipolar parents who had mixed (but nonbipolar) diagnoses (major depression, cyclothymia, ADHD, and ODD). At the end of the study, 71% of the subjects were determined to be divalproex responders based on reductions in aggression as assessed by the Overt Aggression Scale.

Clonidine

Seventeen outpatients (ages 5–15 years) with CD or ODD received open treatment with clonidine for 1–18 months. Aggression decreased significantly in 15 children (88%). The major side effect of clonidine was drowsiness (Kemph et al. 1993).

Despite controversy over its safety (Swanson et al. 1995; see Appendix), clonidine has often been combined with stimulants to treat comorbid aggression in children with ADHD. In a 2-month randomized comparison of clonidine, methylphenidate, and clonidine combined with methylphenidate in the treatment of 24 children and adolescents (ages 6–16 years) with ADHD and CD or ODD, it was found that all three treatment groups showed significant improvement in oppositional and CD symptoms (Connor et al. 2000). No significant ECG changes were noted.

Children ages 6–14 years with ADHD currently taking methylphenidate were randomly assigned to receive clonidine syrup 0.10–0.20 mg/day ($n = 37$) or placebo ($n = 29$) for 6 weeks (Hazell and Stuart 2003). Analysis showed that significantly more clonidine-treated children than controls were responders on the Conduct subscale (21 of 37 vs. 6 of 29; $P < 0.01$) of the parent-report Conners Behavior Checklist but not the Hyperactive Index subscale (13 of 37 vs. 5 of 29). Compared with placebo, clonidine was associated with a greater reduction in systolic blood pressure measured standing and with transient sedation and dizziness. Clonidine-treated individuals had a greater

reduction in a number of unwanted effects associated with psychostimulant treatment compared with placebo. The findings supported the use of clonidine in combination with psychostimulant medication to reduce conduct symptoms associated with ADHD.

Beta-Blockers

Propranolol

In an open study of 16 patients (ages 4–24 years) with aggressive outbursts treated with propranolol (mean daily dose = 164 mg), 19 patients (63%) showed a significant reduction in aggressive outbursts. Fatigue was the most common side effect (Kuperman and Stewart 1987). In a retrospective study of propranolol (dosage range = 50–1,600 mg/day; median optimal daily dose = 160 mg) for uncontrolled rage outbursts in 30 patients (ages 7–35 years [4 adults]) with organic brain dysfunction, approximately 75% of patients showed moderate to marked improvement in rage outbursts. The most common side effects were somnolence, lethargy, and hypotension (Williams et al. 1982). There was a lack of standardized outcome measures, however, and the wide dosage range is puzzling. Results of this study have never been confirmed by a controlled trial in children or adolescents.

Nadolol

Nadolol is a beta-blocker that does not cross the blood–brain barrier; thus, any clinical effect would be due to its action on the peripheral sympathetic nervous system. Its use as an adjunctive pharmacological treatment for aggression and/or inattention/overactivity was studied in a developmentally delayed child, adolescent, and young adult population (Connor et al. 1997). Twelve subjects (mean age = 13.8 years, range = 9–24 years) completed a 5-month trial of nadolol (mean dosage = 109 mg/day, range = 30–220 mg/day) with baseline, weekly, and end-of-study assessments of aggression and inattention/overactivity. Ten subjects (83%) showed clinical improvement while receiving nadolol. Significant improvements were noted on observer-rated overt categorical aggression, severity of illness, and global impressions of improvement. No significant effects were found for inattention/overactivity, although blood pressure and pulse were significantly reduced. Nadolol was well tolerated, with few side effects. While the study suggests usefulness of this agent in treating aggression, the sample size was small and no controlled trials have been performed. The effectiveness of beta-blockers in the treatment of aggression must be viewed as unproven; beta-blockers can induce asthma attacks and significant bradycardia so should be used only as a last resort.

Clinical Recommendations for Disruptive Behavior Disorders and Aggression

The Center for the Advancement of Children's Mental Health at Columbia University joined with the New York State Office of Mental Health to develop guidelines for treatment of aggression, which led to the Treatment Recommendations for the Use of Antipsychotics for Aggressive Youth (TRAAY) (Pappadopulos et al. 2003; Schur et al. 2003). These recommendations call first for a thorough psychiatric evaluation of the child with severe aggression. Next, a psychosocial intervention should be used first when the aggression is the primary problem (such as in ODD/CD or intermittent explosive disorder). The clinician should then treat any primary condition, such as ADHD, psychosis, or mood disorder, that may be causing or contributing to the aggression. If the aggression does not respond to these steps, then an atypical antipsychotic should be used. Different atypical antipsychotics should be tried as monotherapy before moving to polypharmacy (e.g., adding a classic mood stabilizer such as lithium or divalproex to the antipsychotic). Monitoring of weight and laboratory measures of glucose, cholesterol, and triglycerides is mandatory (Correll and Carlson 2006).

Alpha agonists may be used in more mild aggression or temper outbursts since their effect size on aggression is more modest (Hazell and Stuart 2003). Beta-blockers should be used only as a last

resort. Recently, the Intercontinental Schizophrenia Outpatient Health Outcomes study compared the response of aggressiveness to clozapine, olanzapine, quetiapine, risperidone, or haloperidol in a very large sample of adult schizophrenia patients (*n* = 3,135) who had 6 months of monotherapy (Bitter et al. 2005). Olanzapine and risperidone were significantly superior to haloperidol and clozapine for reducing aggression. Given that typical antipsychotics have higher rates of tardive dyskinesia than atypical antipsychotics (Correll et al. 2004) and now have been shown to be less effective for the treatment of aggression, the use of typical antipsychotics to treat children with aggression is contraindicated.

TOURETTE'S SYNDROME

The prevalence of Tourette's syndrome is estimated to be 0.7% in children (Comings et al. 1990). Tourette's syndrome is characterized by multiple motor tics and by one or more vocal tics that occur frequently for longer than 1 year (American Psychiatric Association 2000). The average age at onset of tics is at about age 5 years. Tics tend to increase in severity in the prepubertal years, but they diminish significantly by age 18 years (Leckman 2002).

α-Adrenergic Receptor Agonists

Clonidine

Two of three controlled studies support the efficacy of clonidine treatment for Tourette's syndrome. In a 12-week double-blind, placebo-controlled trial, 39 children and adolescents with Tourette's syndrome were randomly assigned to clonidine (dosage range = 3.2–5.7 μg/kg/day; mean daily dose = 4.4 μg/kg) or placebo. The group treated with clonidine had a statistically significant greater improvement on Tourette's Syndrome Global Scale (TSGS) scores than did the group receiving placebo. Clonidine was most effective for motor tics and tics that were noticeable to others. The most common side effects were sedation, fatigue, dry mouth, dizziness, and irritability (Leckman et al. 1991).

Thirteen children and adolescents (ages 9–16 years) with Tourette's syndrome were randomly assigned to a 20-week single-blind, placebo-controlled trial of clonidine (mean daily dose = 5.5 μg/kg). Six patients (46%) had a positive response to clonidine, as determined by TSGS scores. The most common side effects of clonidine were sedation, headache, and early-morning awakening (Leckman et al. 1985).

Twenty-four children and adolescents with Tourette's syndrome completed a double-blind crossover study that included two 12-week treatment phases—one phase with clonidine (either 0.0075 mg/kg/day or 0.015 mg/kg/day) and the other phase with placebo. However, in this study, clonidine did not significantly reduce motor tics, vocalizations, or behaviors. The most common side effects were sedation, dry mouth, and restlessness. There were no clinically significant changes in blood pressure or pulse (Goetz et al. 1987).

A retrospective study of 53 children and adolescents (ages 5–18 years) with Tourette's syndrome was conducted to determine predictors of response to clonidine treatment. Patients who had a longer duration of vocal tics had a good behavioral response to clonidine. Of 47 patients who received clonidine for tic control, 57% had a good tic response. The authors concluded that clonidine is a useful medication for 40%–60% of patients with mild to moderate tics (Lichter and Jackson 1996).

Clonidine was compared with risperidone in the treatment of children and adolescents with Tourette's syndrome (Gaffney et al. 2002). Following a single-blind placebo lead-in, 21 subjects (ages 7–17 years) were randomly assigned to 8 weeks of double-blind treatment with clonidine or risperidone. Research scales evaluated tics and comorbid obsessive-compulsive and attention-deficit/hyperactivity symptoms. Risperidone (mean dosage = 1.5 ± 0.9 mg/day) and clonidine (mean dosage = 0.175 ±

0.075 mg/day) appeared equally effective in the treatment of tics in an intent-to-treat analysis, as rated by the YGTSS. Risperidone produced a mean reduction in the YGTSS of 21%; clonidine produced a 26% reduction. There was a nonsignificant trend for subjects with comorbid obsessive-compulsive symptoms to respond better to risperidone (63%) than to clonidine (33%). Both treatments caused mild sedation that resolved with time; no clinically significant extrapyramidal symptoms were observed.

Guanfacine

Scahill et al. (2001) randomly assigned 34 children (mean age 10.4 years) with comorbid ADHD and tic disorders to receive either placebo or guanfacine for 8 weeks in a double-blind fashion. Tic severity declined by an average of 31% in the guanfacine group versus 0% in the placebo group. Globally, 9 of 17 subjects were rated as much or very much improved on the CGI compared with none so rated in the placebo group. One subject withdrew due to sedation; guanfacine was associated with insignificant decreases in blood pressure. In contrast, in a 4-week double-blind, placebo-controlled study of guanfacine in 24 children (ages 6–16 years) with Tourette's syndrome, there was no significant improvement in tic severity for guanfacine-treated patients compared with placebo-treated patients (Cummings et al. 2002).

Lofexidine

Lofexidine is an α_2 agonist used for the treatment of opiate withdrawal in the United Kingdom, similar to the use of clonidine in the United States. Forty-four medication-free subjects (41 boys and 3 girls; mean age = 10.4 years) with ADHD, combined type, and a tic disorder participated in an 8-week trial of lofexidine (Niederhofer et al. 2003). Lofexidine was associated with a mean improvement of 41% in the total score on the teacher-rated ADHD Rating Scale, compared with 7% improvement for placebo. Eleven of 22 subjects who received lofexidine were blindly rated on the CGI-I as either much improved or very much improved, compared with none of 22 subjects who received placebo. Tic severity decreased by 27% in the lofexidine group, compared with 0% in the placebo group. One lofexidine subject withdrew because of sedation at week 4. Lofexidine was associated with insignificant decreases in blood pressure and pulse. Lofexidine appears to be a safe and effective treatment for children with tic disorders and ADHD, although it is not clear if it has any advantage over clonidine or guanfacine.

Atypical Antipsychotics

Risperidone

Risperidone is the atypical antipsychotic most studied for the treatment of Tourette's syndrome and tic disorders. Risperidone was compared with pimozide in a 12-week double-blind, placebo-controlled multicenter study of 50 patients (ages 10–65 years) with Tourette's syndrome. Patients treated with both risperidone (mean daily dose = 3.8 mg) and pimozide (mean daily dose = 2.9 mg) showed significant improvement on the Tourette's Syndrome Severity Scale (TSSS; Shapiro et al. 1988). Fourteen of 26 patients (54%) treated with risperidone and 9 of 24 patients (38%) treated with pimozide had very mild or no symptoms on the TSSS at endpoint. Fewer patients treated with risperidone than with pimozide reported extrapyramidal side effects. Side effects common to both treatment groups were depression, fatigue, and somnolence (Bruggeman et al. 2001).

In a double-blind, placebo-controlled trial in 48 adolescent and adult outpatients (ages 14–49 years) with Tourette's syndrome, patients were randomly assigned to risperidone (dosage range = 1–6 mg/day; median daily dose = 2.5 mg) or placebo for an 8-week trial. Risperidone was significantly superior to placebo on the global severity rating of the TSSS. Adverse effects more common in the group treated with risperidone than in the group treated with placebo were hypokinesia, tremor, fatigue, and somnolence (Dion et al. 2002).

The efficacy of risperidone was further assessed in an 8-week randomized, double-blind, placebo-controlled trial using the Total Tic score of the YGTSS as the primary outcome variable (Scahill et al. 2003). Thirty-four medication-free subjects (26 children and 8 adults) ranging in age from 6 to 62 years (mean = 19.7 ± 17.0 years) participated. After 8 weeks of treatment, the 16 subjects receiving risperidone (mean daily dose = 2.5 ± 0.85) showed a 32% reduction in tic severity from baseline, compared with a 7% reduction for the 18 subjects receiving placebo (P = 0.004). The 12 children randomly assigned to risperidone showed a 36% reduction in tic symptoms, compared with an 11% decrease in the 14 children on placebo (P = 0.004). Two children on risperidone showed acute social phobia, which resolved with dose reduction in 1 subject but resulted in medication discontinuation in the other. A mean increase in body weight of 2.8 kg was observed in the risperidone group compared with no change in placebo (P = 0.0001). No extrapyramidal symptoms and no clinically significant alterations in cardiac conduction times or laboratory measures were observed.

Risperidone was compared to pimozide in the treatment of children and adolescents with tic disorders in a randomized, double-blind crossover study (Gilbert et al. 2004). Nineteen children (ages 7–17 years) with Tourette's syndrome or chronic motor tic disorder were randomly assigned to 4 weeks of treatment with pimozide or risperidone, followed by the alternate treatment after a 2-week placebo washout. The primary efficacy outcome measure was change in tic severity assessed by the YGTSS. Compared to pimozide treatment, risperidone treatment was associated with significantly lower tic severity scores (YGTSS: baseline 43.3 ± 17.5, pimozide 34.2 ± 14.2, risperidone 25.2 ± 13.6; P = 0.05). Weight gain during the 4-week treatment periods was greater for risperidone (mean 1.9 kg) than pimozide (1.0 kg). No patient suffered a serious adverse event, but 6 of 19 subjects failed to complete the protocol. Neither medication was associated with ECG changes. While risperidone appeared superior to pimozide for tic suppression, it was associated with greater weight gain.

Most recently, a 6-week open-label study examined the effects of risperidone in the treatment of chronic tic disorder or Tourette's disorder in children and adolescents (Kim et al. 2005). The subjects were 15 young children and adolescents (mean age 10 ± 2.4 years). Seven subjects were diagnosed with Tourette's disorder and 8 subjects with chronic tic disorder. Ten of the 15 subjects were administered risperidone for the first time, and 5 of the 15 subjects had been previously treated with traditional drugs (haloperidol or pimozide). Clinical responses were measured at baseline and after 1, 3, and 6 weeks of drug treatment by using the Korean version of the YGTSS and the Global Assessment of Functioning Scale. The mean dosage of risperidone was 0.53 ± 0.13 mg for the first week, 0.90 ± 0.28 mg for the third week, and 1.23 ± 0.37 mg for the sixth week. Comparison between periods according to the Korean version of the YGTSS showed significant differences (P <0.01) between the first week and the third week. After 6 weeks of administration, tic severity scale scores revealed a 36% reduction in overall tic symptoms; 13 of the 15 subjects showed significant improvement, 1 subject showed no difference in symptoms, and 1 subject showed worsening of symptoms.

Olanzapine

An open-label trial was performed to explore efficacy and safety of olanzapine for treatment of Tourette's disorder (Budman et al. 2001). Ten adult patients (ages 20–44 years) with Tourette's disorder were treated using an open-label, flexible-dosing schedule for 8 weeks. Three patients who continued olanzapine were reevaluated after 6 months. Three subjects were psychotropic medication naive, 5 patients experienced intolerable side effects with conventional antipsychotics, and 2 patients had a past history of successful response to conventional antipsychotics. Tic severity was rated by the YGTSS; weight, vital signs, and adverse effects were assessed weekly. Two of 10 patients prematurely discontinued olanzapine owing to excessive sedation. Of 8 patients who completed the 8-week trial, 4 (50%) demonstrated reduction of global tic severity scores by ≥20 points, and 6 (75%) demonstrated reductions by ≥10 points. Sedation, weight gain, increased appetite, dry mouth, and transient

asymptomatic hypoglycemia were the most common side effects. Tic improvements were maintained in 3 patients reassessed 6 months later. Final olanzapine dosages ranged from 2.5 mg to 20 mg daily (mean = 10.9 mg/day).

The effects of olanzapine on aggressive behavior and tic severity were further examined in children with Tourette's syndrome, as described above in the aggression section of this chapter (Stephens et al. 2004). Olanzapine significantly reduced tics in the 10-week trial.

Ziprasidone

In an 8-week double-blind, placebo-controlled trial, 28 children and adolescents (ages 7–17 years) with Tourette's syndrome were randomly assigned to ziprasidone (dosage range = 10–40 mg/day; mean daily dose = 28 mg) or placebo. The group treated with ziprasidone had a statistically significant reduction in scores on the YGTSS, compared with the group treated with placebo. The most common adverse event was somnolence. No clinically significant changes in vital signs or ECG parameters were reported (Sallee et al. 2000).

Nonetheless, concerns continue to be raised about possible cardiovascular effects of ziprasidone. A sudden death occurred in a child who participated in a clinical trial of ziprasidone for Tourette's (Scahill et al. 2005). Despite the fact that a single dose of ziprasidone did not produce abnormal ECG changes (Sallee et al. 2006), ECG changes were found in the children treated with ziprasidone for Tourette's syndrome in a long-term open-label safety study (Blair et al. 2005). In 20 children treated with ziprasidone, there were statistically significant changes from baseline to peak values in heart rate, pulse rate, and QTc intervals, but not in QRS complex width. The mean QTc prolongation was 28 ± 26 milliseconds and not related to dose ($r = 0.16$, $P = .07$). The peak QTc of three subjects reached or exceeded 450 milliseconds; one subject experienced a 114-millisecond prolongation. These findings, occurring at doses low by current treatment standards, suggest that electrocardiographic monitoring is warranted when prescribing ziprasidone to children.

Quetiapine

The short-term safety and effectiveness of quetiapine in the treatment of children and adolescents with Tourette's disorder were studied in an 8-week open-label trial that included 12 subjects with a mean age of 11.4 ± 2.4 years (Mukaddes and Abali 2003). Clinical responses, as measured by the Turkish version of the YGTSS, revealed a statistically significant reduction in tic scores ranging from 30% to 100%. The mean dosage of quetiapine at the end of the study was 72.9 ± 22.5 mg/day. Three subjects complained of sedation in the first week of treatment.

In a retrospective study of clinic patients, 12 patients (ages 8–18 years) with Tourette's syndrome received quetiapine therapy at a starting dose of 25 mg/day, which was increased to a mean dosage of 175.0 ± 116.6 mg/day by the eighth week of the study (Copur et al. 2007). The YGTSS score, which was 21.6 ± 4.0 at baseline, showed significant decreases at 4 and 8 weeks (reducing to 7.5 ± 7.4 and 5.6 ± 8.1, respectively; $P < 0.003$). Routine laboratory parameters and serum prolactin levels were all normal and did not change throughout treatment. Mild but significant increases in both body weight and BMI at 4 and 8 weeks compared with baseline were observed. No controlled trials of quetiapine in the treatment of tic disorders have been performed.

Aripiprazole

Murphy et al. (2005) reported six cases of children and adolescents (age range = 8–19 years, mean age = 12.1 years) who had comorbid tic disorder and OCD and were treated with aripiprazole (mean dosage = 11.7 mg/day; range = 5–20 mg/day) for 12 weeks. The subjects experienced a mean reduction of 56% in the severity of their tics as assessed by YGTSS. Similarly, Yoo et al. (2006) treated 15 children and adolescents with tic disorder with aripiprazole (mean dosage = 10.89 mg/day; range = 12.5–15 mg/day) and reported a mean reduction of 40% in YGTSS scores; side

effects were minimal. Two subjects experienced nausea, 1 had weight gain, and 1 suffered sedation that responded to dosage reduction.

A case series of 11 consecutive patients with Tourette's syndrome (age range = 7–50 years; mean age = 7 years) were treated with aripiprazole; the majority of these had been refractory to other treatments with other antipsychotics (Davies et al. 2006). Ten of the 11 patients who were treated with aripiprazole improved, although to variable degrees. In the majority of patients, response was sustained with aripiprazole doses ranging from 10 to 20 mg daily. Side effects were mild and transient.

Typical Antipsychotics: Pimozide and Haloperidol

In a controlled trial comparing pimozide, haloperidol, and placebo in 57 patients (ages 8–65 years) with Tourette's syndrome, both active treatments were significantly more effective than placebo, and haloperidol was slightly more effective than pimozide. No significant differences in side effects were found between haloperidol and pimozide (Shapiro et al. 1989).

Sallee et al. (1997) conducted a 24-week double-blind, placebo-controlled crossover study of haloperidol (mean daily dose = 3.5 mg) and pimozide (mean daily dose = 3.4 mg) in 22 children and adolescents (ages 7–16 years) with Tourette's syndrome. Only pimozide was significantly superior to placebo on TSGS scores. There was a threefold higher frequency of serious side effects (depression, anxiety, and severe dyskinesias) with haloperidol (41%) than with pimozide (14%) in these youths. Extrapyramidal side effects were reported significantly more often with haloperidol than with pimozide.

In an open clinical trial in 31 patients (ages 10–50 years) with Tourette's syndrome treated for, on average, 1–2 years, 23 patients (74.2%) receiving pimozide, compared with 14 patients (45.2%) receiving haloperidol, had significant clinical improvement (Shapiro et al. 1983).

Long-term (6–84 months) treatment with pimozide (0.5–9 mg/day) was reported to produce a good clinical response in 81% of 65 patients (ages 6–54 years) (Regeur et al. 1986). A 1- to 15-year follow-up of 33 patients (ages 9–50 years) with Tourette's syndrome treated with pimozide (2–18 mg/day), haloperidol (2–15 mg/day), or no medications found that significantly more patients discontinued haloperidol than pimozide because of adverse side effects, especially dyskinesias and dystonias (Sandor et al. 1990). Thus, pimozide appears superior to haloperidol for treatment of tics.

Other Agents

Metoclopramide

Metoclopramide is a dopamine antagonist used for the treatment of gastroesophageal reflux; it blocks dopamine$_2$ receptors in the striatum but not in the cerebral cortex. Acosta and Castellanos (2004) reported that metoclopramide improved tics in 10 patients with tic disorders, with negligible adverse events. Nicolson et al. (2005) randomly assigned 27 children and adolescents with tic disorders to receive either placebo or metoclopramide in an 8-week double-blind, placebo-controlled trial. Metoclopramide was started at 5 mg/day and titrated to a maximum dose of 40 mg/day. In the active-drug group, there was a 39% reduction in tics versus a 13% reduction on placebo (P = 0.001). No extrapyramidal side effects were reported, and side effects were not different between metoclopramide and placebo. Further large-scale double-blind, placebo-controlled trials of this agent are needed.

Nicotine

In a double-blind, placebo-controlled trial, 74 patients (mean age = 11 years) with Tourette's syndrome who received haloperidol were randomly assigned to adjunctive transdermal nicotine (7

mg/24 hours) or placebo. Transdermal nicotine was significantly superior to placebo in reducing symptoms of Tourette's syndrome (Silver et al. 2001b). A transdermal nicotine patch (7 mg/24 hours) as adjunctive treatment to antipsychotics was shown to produce significant improvement in tic severity for 16 children and adolescents with Tourette's syndrome (Silver et al. 1996).

In a trial of nicotine gum (2 mg) added to haloperidol treatment, 10 youths with Tourette's syndrome had marked reduction in tics (Sanberg et al. 1989). In a follow-up study with 10 additional patients, nicotine gum added to haloperidol was shown to reduce tic frequency during and after 1 hour of gum chewing (McConville et al. 1991). In a controlled study comparing nicotine gum plus haloperidol, nicotine gum only, and placebo gum in 19 patients with Tourette's syndrome, the combined treatment of nicotine gum plus haloperidol showed the greatest reduction in tic frequency and severity (McConville et al. 1992).

Mecamylamine

Mecamylamine is a nicotine receptor antagonist that has been used as an antihypertensive agent and for smoking cessation. In an 8-week double-blind, placebo-controlled multicenter trial, 61 children and adolescents (ages 8–17 years) with Tourette's syndrome were randomly assigned to mecamylamine (dosage range = 2.5–7.5 mg/day) or placebo (Silver et al. 2001a). No significant difference was found on ratings of Tourette's symptoms between the group treated with mecamylamine and the group treated with placebo. The most common side effects were weakness, vomiting, muscle twitching, hypersomnia, and dysphoria.

In one retrospective open-label study of 19 children and adolescents and 5 adults with Tourette's syndrome treated with mecamylamine (2.5–6.25 mg/day) for 8–550 days, a significant improvement in severity of illness from baseline was reported (Macaluso et al. 2000). In another retrospective study that included 9 children with Tourette's syndrome, concomitant use of mecamylamine was found to improve symptoms of Tourette's syndrome (Sanberg et al. 1998). Given that this agent is rarely used in adults for its indicated purposes, further controlled studies are needed before it is used widely for tic disorders.

Common Comorbid Conditions

Obsessive-Compulsive Disorder

Tourette's syndrome is frequently comorbid with OCD (Leckman 2002), necessitating treatment of both conditions. The Pediatric OCD Treatment Study (POTS) (March et al. 2007) randomly assigned 112 children with OCD (17 of whom had comorbid tics) to CBT, sertraline, a combination of sertraline and CBT, or placebo. In patients without tics, combination therapy was superior to CBT alone which in turn was superior to sertraline; all treatments were superior to placebo. In the small subset of patients with tics, sertraline was not superior to placebo for the treatment of OCD, but combined treatment was. An earlier study randomly assigned children with OCD and tics to either sulpiride (a typical antipsychotic) or fluvoxamine for a double-blind treatment period, followed by a single-blind period of combined treatment (George et al. 1993). Fluvoxamine, whether alone or with sulpiride, did not ameliorate tics but was effective for OCD. In contrast, sulpiride did reduce tics when used as monotherapy.

Attention-Deficit/Hyperactivity Disorder

ADHD is a common comorbid disorder with Tourette's syndrome. Treatment of both disorders is often necessary in children. Although prior literature has cautioned against the use of psychostimulants to treat ADHD in Tourette's syndrome because of potential exacerbation of tics, recent studies do not support this view. Methylphenidate in low to moderate doses did not produce a clinically significant increase in motor tics for youths with tic disorders or Tourette's disorder and ADHD (Castellanos et al.

1997; Gadow et al. 1995). In a 2-year longitudinal follow-up of 29 children with ADHD and tic disorders (predominantly Tourette's syndrome) treated with methylphenidate, there was no evidence that methylphenidate increased motor or vocal tics (Gadow et al. 1999).

In a 16-week double-blind, placebo-controlled multicenter study, 136 youths with tic disorder and ADHD were randomly assigned to clonidine (mean daily dose = 0.25 mg), methylphenidate (mean daily dose = 26 mg), combination methylphenidate plus clonidine (mean daily dose = 0.28 mg), or placebo. Compared with placebo, active treatment groups showed a significant reduction in tic severity, with combination treatment showing the greatest improvement in tics (Tourette's Syndrome Study Group 2002). This is in contrast to an earlier smaller (*N* = 37) double-blind, placebo-controlled trial which found that clonidine did not reduce tic severity in children with Tourette's syndrome and ADHD (Singer et al. 1995).

Atomoxetine was studied in children and adolescents (ages 7–17 years) who met criteria for ADHD and Tourette's syndrome or chronic motor tic disorder (Allen et al. 2005). Patients were randomly assigned to double-blind treatment with placebo (*n* = 72) or atomoxetine (0.5–1.5 mg/kg/day, *n* = 76) for up to 18 weeks. Atomoxetine treatment was associated with greater reduction of tic severity at endpoint relative to placebo, approaching significance on the YGTSS total score (*P* = 0.063) and Tic Symptom Self-Report total score (*P* = 0.095) and achieving significance on the Clinical Global Impressions (CGI) tic/neurological severity scale score (*P* = 0.002). Atomoxetine was effective for ADHD symptoms and clearly did not exacerbate tic symptoms.

In a double-blind, placebo-controlled trial with 37 children with Tourette's syndrome and ADHD, desipramine, compared with clonidine, was reported to be more effective for both disorders (Singer et al. 1995). Compared with placebo, desipramine was found to be significantly more effective for the reduction of both tics and ADHD symptoms in 41 children and adolescents (T. Spencer et al. 2002). The earlier noted reports of sudden death limit its use. Nortriptyline has also been reported in retrospective studies to be effective in treating the symptoms of both ADHD and Tourette's syndrome in children and adolescents (T. Spencer et al. 1993).

Clinical Recommendations for Tourette's Syndrome

If a tic is not severe or socially impairing, observation may be in order, as the natural history of tics is to wax and wane; in general, tics improve over time (Leckman 2002). Often, psychosocial treatment such as habit reversal training is highly effective at reducing tics (Piacentini and Chang 2006). If conservative treatment fails, use of an alpha agonist would be desirable, owing to the risk of weight gain and dyslipidemia with atypical antipsychotics. Due to lower efficacy and higher risk of tardive dyskinesia with typical antipsychotics, the atypical antipsychotics are preferred. Haloperidol and pimozide should be used only as a last resort when several atypical agents have failed.

In children with comorbid ADHD, a stimulant can be used, but a nonstimulant is indicated if the stimulant exacerbates tics (Pliszka et al. 2006a). Often stimulants must be combined with alpha agonists or antipsychotics to control both the ADHD and the tics (Pliszka et al. 2006a; Tourette's Syndrome Study Group 2002). In children with OCD and comorbid tics, CBT or CBT combined with a serotonin reuptake inhibitor should be tried first before proceeding with treatment of the tics with alpha agonists or antipsychotics (March et al. 2007).

SCHIZOPHRENIA

The prevalence of schizophrenia in children younger than 13 years is very rare; however, the prevalence rises in adolescence, with peak onset from 15 to 30 years (McClellan and Werry 2001). The clinical features of the disorder are similar in youths and adults, and the same DSM-IV-TR criteria are used to establish a diagnosis (American Psychiatric Association 2000). The outcome of childhood-onset schizophrenia is reported to be poor (Eggers and Bunk 1997). Typical antipsychotics

have been studied in small randomized, controlled trials of youths with schizophrenia. Recently, the results of large controlled multicenter trials of atypical antipsychotics in adolescents with schizophrenia have been reported.

Atypical Antipsychotics

Clozapine

There has been one 6-week double-blind, placebo-controlled comparison of clozapine and haloperidol for 21 children and adolescents (ages 6–18 years) with schizophrenia (Kumra et al. 1996). Clozapine (mean dosage = 176 mg/day; range = 25–525 mg/day) was significantly superior to haloperidol (mean dosage = 16 mg/day; range = 7–27 mg/day) in reducing positive and negative symptoms of schizophrenia. Clozapine improved interpersonal functioning and enabled patients to live in a less restrictive setting. Side effects, however, were significant with clozapine. One patient had a seizure, and 3 patients were given anticonvulsants after they became more irritable and aggressive and experienced epileptiform changes on EEG. Mild to moderate neutropenia, weight gain, and sinus tachycardia were the other major side effects. One-third of the clozapine group discontinued use of the medication. One patient was discontinued from the haloperidol treatment group because of early signs of neuroleptic malignant syndrome.

Clozapine was found to be effective for the treatment of aggressive behavior in children and adolescents with treatment-refractory schizophrenia (Kranzler et al. 2005). Twenty youths received clozapine (mean daily dose = 476 mg at week 24) in an open-label study. A significant reduction in the frequency of receiving emergency oral medications and emergency injectable medications, as well as a decreased use of seclusion, was found on clozapine compared with before clozapine treatment.

Olanzapine

A positive double-blind, placebo-controlled multicenter study of olanzapine (mean dosage = 11.1 mg/day) for the treatment of adolescents with schizophrenia was recently reported (Kryzhanovskaya et al. 2006). One hundred adolescents were randomly assigned to olanzapine (n = 72) or placebo (n = 35) for a 6-week trial. Olanzapine-treated adolescents had significant improvements on the Brief Psychiatric Rating Scale for Children (BPRS-C; Overall and Pfefferbaum 1984) and CGI-S compared with the placebo group. There was no significant difference in response rate (≥30% decrease in BPRS-C and CGI severity ≤3) between olanzapine (37.5%) and placebo (25.7%) groups. Significantly more olanzapine-treated adolescents had treatment-emergent high AST/SGOT, ALT/SGPT, and prolactin and low bilirubin and hematocrit during treatment. There was a significant increase in fasting triglycerides at endpoint in the olanzapine-treated adolescents.

In an 8-week open-label trial of olanzapine (mean dosage = 17.5 mg/day) in the treatment of eight children and adolescents with schizophrenia, there was a 17% improvement on the BPRS, a 27% improvement on the Scale for the Assessment of Negative Symptoms, and a 1% improvement on the Scale for the Assessment of Positive Symptoms (Kumra et al. 1998). The magnitude of the effect size for olanzapine was reported to be greater than that for clozapine. The most common side effects reported for olanzapine were increased appetite, constipation, nausea, vomiting, headache, somnolence, insomnia, sustained tachycardia, transient elevation of liver transaminase levels, increased agitation, and difficulty concentrating. Average weight gain during a 6-week period of olanzapine was 3.4 kg.

In an 8-week open-label prospective trial of olanzapine (mean total daily dose = 12.4 mg/day) in 16 adolescents (age range = 12–17 years), statistically significant reductions in total PANSS scores and improvement in global functioning were found (Findling et al. 2003b).

Risperidone

The first positive double-blind, placebo-controlled multicenter trial of risperidone in the treatment of adolescents with schizophrenia was recently reported (Haas et al. 2007). One hundred sixty patients were randomly assigned to risperidone 1–3 mg/day (n = 55), risperidone 4–6 mg/day (n = 51), or placebo (n = 54) for a 6-week trial. Both dosage ranges of risperidone were significantly superior to placebo on the primary efficacy measure, PANSS total change score at endpoint. The most common adverse events were somnolence (24%), agitation (15%), and headache (13%) in the risperidone 1–3 mg/day group. Extrapyramidal disorder (16%), dizziness (14%), and hypertonia (14%) were the most common adverse events in the risperidone 4–6 mg/day group. The investigators concluded that the overall risk–benefit ratio favored the lower dosage range of risperidone.

Aripiprazole

The results of a large double-blind, placebo-controlled multicenter trial of aripiprazole for the treatment of schizophrenia in adolescents were recently reported (Findling et al. 2007). Three hundred and two patients were randomly assigned to aripiprazole 10 mg, aripiprazole 30 mg (after 5- or 11-day titration), or placebo over a 6-week period. Both the 10-mg and 30-mg doses of aripiprazole showed statistically significant differences from placebo on the PANSS total score at week 6 (Robb et al. 2007). The most common adverse events associated with aripiprazole were extrapyramidal disorder, somnolence, and headache.

Quetiapine

No data are available from double-blind, placebo-controlled trials of quetiapine for the treatment of schizophrenia in youth. There have been two open trials assessing the effectiveness of quetiapine in adolescents with psychotic disorders. J. A. Shaw et al. (2001) conducted an 8-week open trial of quetiapine (467 mg/day; range 300–800 mg/day) in 15 adolescents with a diagnosis of psychotic disorder (including 5 with a diagnosis of schizophrenia). Quetiapine significantly reduced psychotic symptoms in these adolescents. Mean weight gain over the 8-week period was 3.4 kg. There were no changes in prolactin and cholesterol levels or in ECG or ophthalmic examination findings. The most common adverse effects were somnolence, agitation, drowsiness, and headache. McConville et al. (2000) assessed the effectiveness of quetiapine in 10 adolescents with psychotic disorders (7 with schizoaffective disorder, 3 with bipolar disorder). Improvement in both positive and negative symptoms was observed during the course of the 25-day inpatient trial.

In a long-term study of an adolescent treated with quetiapine, it was reported that continued improvement in positive symptoms was evident up to 8 months after initiation of treatment, and negative symptoms were still improving at 18 months. After 28 months of treatment, there were no apparent adverse effects (Hayden 2001).

Comparison of Atypical Antipsychotics

In an open-label 12-week trial, risperidone (mean dosage = 1.6 mg/day) was compared with olanzapine (mean dosage = 8.2 mg/day) in the treatment of 25 children with schizophrenia (Mozes et al. 2006). Both groups showed similar significant improvement in the PANSS total and subscale scores. Eleven (91.7%) of the olanzapine-treated children and 9 (69.2%) of the risperidone-treated children completed the 12-week study. Both groups showed significant weight increase from baseline to endpoint (mean 5.8 kg for olanzapine group and mean 4.5 kg for risperidone group).

In an 8-week double-blind study, 50 youths (ages 8–19 years) with psychotic disorders were randomly assigned to risperidone (mean dosage = 4 mg/day), olanzapine (mean dosage = 12.3 mg/day), or haloperidol (mean dosage = 5 mg/day) (Sikich et al. 2004). Eighty-eight percent of patients treated with olanzapine, 74% treated with risperidone, and 53% treated with haloperidol met response criteria (CGI-I scores of much or very much improved and at least a 20% reduction in BPRS-C total score). Sedation, extrapyramidal symptoms, and weight gain were the most common

side effects.

Clozapine was compared with olanzapine in an 8-week double-blind, randomized trial (P. Shaw et al. 2006). Twenty-five youths (ages 7–16 years) with schizophrenia who were resistant to treatment with at least two antipsychotics participated in the trial. Clozapine (mean dosage = 327 mg/day) showed significant improvement in all outcome measures, compared with olanzapine (mean dosage = 19.1 mg/day), which showed improvement on some outcome measures. Improvement in negative symptoms was significantly greater for the clozapine group. Clozapine produced more adverse events, including nocturnal enuresis, tachycardia, and hypertension. Prolactin levels showed significantly greater increases in the olanzapine group. At 2-year follow-up, 15 patients who were receiving clozapine had continued clinical improvement, although lipid abnormalities (*n* = 6) and seizures (*n* = 1) had occurred.

Typical Antipsychotics

Haloperidol

Haloperidol has been compared with placebo and other typical antipsychotics in controlled trials in youths. In a 10-week double-blind, placebo-controlled crossover study, the safety and efficacy of haloperidol were assessed in 12 hospitalized children (ages 5–12 years) with schizophrenia. Haloperidol (optimal dosage range = 0.5–3.5 mg/day) was significantly superior to placebo in improving overall clinical functioning and reducing ideas of reference, delusions, and hallucinations. Common side effects were acute dystonic reaction, drowsiness, and dizziness (E. K. Spencer et al. 1992).

Haloperidol was compared with fluphenazine in a 12-week double-blind study of 30 outpatients (ages 6–12 years) with schizophrenia. Both haloperidol and fluphenazine were very effective in improving symptoms. There was no significant difference between their overall efficacy; 87% of haloperidol patients and 93% of fluphenazine patients were much or very much improved. The most common side effects were extrapyramidal symptoms, which occurred more frequently with fluphenazine than with haloperidol (Engelhardt et al. 1973). In an 8-week double-blind comparison trial of haloperidol and fluphenazine in 60 children (ages 5–12 years) with schizophrenia, both medications were effective in improving symptoms; however, haloperidol was more effective than fluphenazine in reducing provocativeness and autism (Faretra et al. 1970).

Haloperidol and loxapine were compared in a 4-week double-blind, placebo-controlled study of 75 adolescent inpatients with schizophrenia. Both haloperidol and loxapine were significantly superior to placebo, and there was no significant difference in efficacy between the two medications. Response rates (based on CGI improvement) were 87.5% for loxapine, 70% for haloperidol, and 36.4% for placebo. Common side effects were sedation, extrapyramidal symptoms, and somnolence (Pool et al. 1976).

Thiothixene

Thiothixene was compared with thioridazine in a 6-week single-blind study of 21 adolescent inpatients with schizophrenia. Thiothixene (optimal mean dosage = 16.2 mg/day) and thioridazine (optimal mean dosage = 178 mg/day) were equally effective in controlling symptoms, although most of the adolescents continued to be quite impaired. Thiothixene was less sedating than thioridazine (Realmuto et al. 1984). Thiothixene was also compared with trifluoperazine in an 8-week double-blind study of 16 children (ages 8–15 years) with schizophrenia (Wolpert et al. 1967). The effects of both medications were similar in terms of decreasing avoidance behavior, reducing stereotypic behavior, and increasing peer socialization. Side effects were minimal in both groups.

In a single-blind study, thiothixene (10–24 mg/day) was administered to 18 children (ages 5–13

years) with schizophrenia. All patients experienced global clinical improvement, with significant improvement noted in motor activity, stereotyped behavior, coordination, sleeping, affect, exploratory behavior, concentration, eating habits, and range of communication. Common side effects were extrapyramidal symptoms and increased salivation (Waizer et al. 1972).

Trifluoperazine

A study of four children with schizophrenia who received trifluoperazine (4 mg/day) reported that the medication had little influence in improving classroom behavior for three of the four children (Simpson 1977).

Pimozide

Pimozide (dosage range = 1–2 mg/day) produced improvement in affective contact and social behavior in youths with schizophrenia in a small open study followed by placebo discontinuation (Pangalila-Ratulangi 1973).

Clinical Recommendations for Schizophrenia

Both typical and atypical antipsychotics have demonstrated some effectiveness in the treatment of schizophrenia in youths, although the sample sizes have been small in the trials of typical antipsychotics. Given fewer reported extrapyramidal side effects and tardive dyskinesia with atypical antipsychotics, it would be reasonable to initiate treatment with an atypical antipsychotic for a child with schizophrenia. Clozapine, however, should not be initiated unless at least two other antipsychotics have been tried without success. It is important to monitor weight and metabolic parameters for children who receive atypical antipsychotics.

Antipsychotics should be administered for a period of no less than 4–6 weeks at adequate dosages in order to determine efficacy. If there is no response or intolerable side effects, then a trial of a different antipsychotic should be initiated (American Academy of Child and Adolescent Psychiatry 2001).

There are no data to guide maintenance treatment. Because the majority of youths will have a second psychotic episode within 5–7 years of stabilization, there is a significant risk of relapse with medication withdrawal (Kumra 2000). It is recommended that first-episode patients receive maintenance pharmacological treatment for 1–2 years after the initial episode, given the risk of relapse (American Academy of Child and Adolescent Psychiatry 2001). If medication discontinuation is attempted, the dosage should be gradually reduced over several months.

AUTISTIC DISORDER AND OTHER PERVASIVE DEVELOPMENTAL DISORDERS

The prevalence of autistic disorder and other pervasive developmental disorders is estimated to be up to 18.7 per 10,000 population (Howlin 2000). Core features of these disorders are impairments in communication and social skills and the restriction of interests and activities (American Psychiatric Association 2000). Associated behavioral features include hyperactivity, stereotypies, attentional problems, self-injurious behavior, aggression, mood lability, anxiety, obsessions, and compulsions. The majority of children with autistic disorder will continue to have significant social and communication impairments throughout adulthood, although some individuals will be able to live independently (Buitelaar and Willemsen-Swinkels 2000).

Pharmacotherapy is one component of a treatment plan for children with autism. Although there are controlled studies, open trials, and case reports of a variety of pharmacological agents, no medication has been identified that effectively treats the core symptoms of autism and other pervasive developmental disorders (Tanguay 2000). Pharmacotherapy is aimed at target symptoms in order to increase the ability of these children to participate in educational and other psychosocial interventions (Volkmar et al. 1999).

Atypical Antipsychotics

Risperidone

Risperidone has received FDA approval for the treatment of irritability associated with autistic disorder in children and adolescents, including symptoms of aggression toward others, deliberate self-injuriousness, temper tantrums, and quickly changing moods.

Risperidone was chosen as the first drug to be studied by the Research Units on Pediatric Psychopharmacology (RUPP) network funded by NIMH, which was designed to investigate the safety and efficacy of medications for treating maladaptive symptoms and behaviors associated with autistic disorders (McDougle et al. 2000b). One hundred one children ranging in age from 5 to 17 years with autistic disorder participated in an 8-week double-blind, placebo-controlled trial of risperidone (dosage range = 0.5–3.5 mg/day; mean = 1.8 mg/day). A significantly greater positive response—defined as a 25% decrease in the irritability subscale of the Aberrant Behavior Checklist and a rating of much or very much improved on the CGI-I scale—was found for the risperidone group (69%) compared with the placebo group (12%). Adverse events of increased appetite, fatigue, drowsiness, dizziness, and drooling were more common in the risperidone group than in the placebo group. Mean weight gain was 2.7 kg in the risperidone group and 0.8 kg in the placebo group. An 18-month follow-up showed that the majority of subjects who responded to risperidone during intermediate-length treatment continued to show improvement (McDougle et al. 2004).

In an 8-week double-blind, placebo-controlled trial, 79 children (ages 5–12 years) with autism and other pervasive developmental disorders were randomly assigned to either placebo or risperidone (mean dosage = 1.5 mg/day). Risperidone-treated patients exhibited a 64% improvement over baseline irritability, compared with a 30.7% improvement in placebo-treated subjects (Shea et al. 2004).

In a 6-month placebo-controlled study of 40 children (ages 2–9 years) with autism, risperidone (1 mg/day) decreased aggressiveness, hyperactivity, and irritability and improved social responsiveness and nonverbal communication. Appetite increase, weight gain, sedation, and transient dyskinesias in the risperidone-treated children were reported (Nagaraj et al. 2006).

The long-term effects of risperidone were assessed in youths (ages 5–17 years) with autism spectrum disorders (Troost et al. 2005). Twenty-four youths received risperidone for 6 months, followed by a double-blind discontinuation to placebo or continued risperidone. Risperidone was superior to placebo in preventing relapse, with relapse rates of 25% and 75%, respectively. Weight gain, increased appetite, fatigue, and anxiety were the most common side effects.

Similar rates of relapse were reported after placebo substitution following 4 months of risperidone treatment in 32 children with autism. The relapse rates were 62.5% in the placebo substitution group and 12.5% in those who continued risperidone treatment (Research Units on Pediatric Psychopharmacology Autism Network et al. 2005).

Olanzapine

In a 12-week open-label study of olanzapine (mean dosage = 7.8 mg/day) in eight patients (ages 5–42 years) with autistic disorder or pervasive developmental disorder not otherwise specified, the six patients who completed the trial showed much or very much global improvement (Potenza et al. 1999). Significant improvements were found in hyperactivity, social relatedness, affectual responses, sensory responses, language usage, self-injurious behavior, aggression, irritability, anxiety, and depression. The most significant adverse effects were increased appetite and weight gain in six patients and sedation in three patients.

In a 3-month open study of olanzapine (dosage range = 1.25–20 mg/day) in 25 subjects (ages 6–16

years) with pervasive developmental disorder, significant global improvement was reported. The most common side effect was weight gain (mean = 4.8 kg) (Kemner et al. 2002).

Olanzapine was compared with haloperidol in a 6-week open trial in 12 children (ages 4–11 years) with autistic disorder (Malone et al. 2001). Both the olanzapine treatment (mean dosage = 7.9 mg/day) and the haloperidol treatment (mean dosage = 1.4 mg/day) reduced symptoms of social withdrawal and stereotypies and improved speech and object relations.

Quetiapine

The effectiveness of quetiapine (dosage range = 100–350 mg/day) was assessed in a 16-week open-label trial in six children with autistic disorder (Martin et al. 1999). No significant behavioral improvements were found from baseline to endpoint. Only two subjects completed the full 16 weeks of treatment; subjects terminated early because of nonresponse and sedation. One patient had a possible seizure during the fourth week of treatment; other side effects included behavioral activation, increased appetite, and weight gain.

In a 12-week open-label study of quetiapine of nine adolescents (mean age = 14.6 years) with autistic disorder, only two patients were much or very much improved at study endpoint (Findling et al. 2004). The most common side effects reported were sedation and weight gain.

Ziprasidone

The use of ziprasidone (mean daily dose = 59.23) for the treatment of autistic children, adolescents, and young adults was evaluated in an open-label study of 12 patients (ages 8–20 years) for at least 6 weeks (McDougle et al. 2002). Fifty percent of patients were responders based on a CGI scale rating of much improved or very much improved. Transient sedation was the most common side effect.

Clozapine

A case series of three children with autistic disorder treated with clozapine (up to 100 mg/day) for 3 months reported a 40% improvement in measures of abnormal object relationships, negativism, fidgetiness, and hyperactivity. After 8 months of clozapine treatment (mean daily dose = 200 mg), two of the children showed a substantial improvement in language and communication skills (Zuddas et al. 1996).

Typical Antipsychotics

Haloperidol

Haloperidol has been the most widely studied typical antipsychotic for the treatment of autism in children and adolescents. In double-blind, placebo-controlled studies, haloperidol has been shown to be significantly superior to placebo in reducing maladaptive behaviors and facilitating learning on discrimination tasks (Campbell et al. 1982); in increasing retention of discrimination learning and decreasing maladaptive behaviors in the classroom (L. T. Anderson et al. 1984); in decreasing occurrence of stereotypies and increasing orienting reactions of children (Cohen et al. 1980); and in decreasing hyperactivity, temper tantrums, withdrawal, and stereotypies and increasing relatedness (L. T. Anderson et al. 1989). Optimal dosages of haloperidol in these studies ranged from 0.25 to 4 mg/day. The most common side effects were sedation, increased irritability, and acute dystonic reactions. Weight gain was modest (0.2 kg) in autistic children who received haloperidol 0.25–3.5 mg/day for a 6-month period (Silva et al. 1993).

Haloperidol was compared with behavioral therapy in a double-blind, placebo-controlled trial in 40 children (ages 2–7 years) with autistic disorder (Campbell et al. 1978). For children older than 4.5 years, haloperidol was found to be significantly superior to placebo in reducing the severity of withdrawal behaviors and stereotypies. The combination of behavior therapy and haloperidol was the

most effective in facilitating the acquisition of imitative speech.

The long-term efficacy of haloperidol was assessed in 48 children (ages 2–8 years) with autism who received haloperidol for 6 months (Perry et al. 1989). Haloperidol remained effective throughout the 6-month treatment period, and it was equally effective whether it was given continuously or on a discontinuous schedule consisting of 5 days on haloperidol and 2 days on placebo. Children who had symptoms of irritability, angry and labile affect, and uncooperativeness were the best responders to haloperidol.

Reversible haloperidol-related dyskinesias have been reported in 29% of autistic children (Campbell et al. 1988a). Factors related to the development of haloperidol-induced dyskinesias in acute studies of autistic children include female gender (Campbell et al. 1988a) and prenatal and perinatal complications (Armenteros et al. 1995). In a long-term prospective study of haloperidol treatment for 118 children with autism, withdrawal dyskinesias developed in 40 children (33.9%), with 20 children having more than one dyskinetic episode (Campbell et al. 1997). Female gender, prenatal and perinatal complications, greater cumulative haloperidol dose, and/or longer exposure to haloperidol increased the risk of withdrawal dyskinesias.

Pimozide

Pimozide was compared with haloperidol and placebo in a controlled crossover trial that included 34 children with autistic disorder (Naruse et al. 1982). Pimozide and haloperidol were significantly more effective than placebo in reducing maladaptive behavior, such as lack of interest, self-centeredness, and aggressiveness. There was no significant difference between pimozide and haloperidol. An open study of 8 children treated with pimozide (mean dosage = 4.9 mg/day) reported improved behavioral functioning (Ernst et al. 1992).

Serotonin Reuptake Inhibitors

The only placebo-controlled studies of serotonin reuptake inhibitors are with fluoxetine and fluvoxamine treatment of autistic disorders.

Fluoxetine

The efficacy of liquid fluoxetine was assessed to treat repetitive behaviors in children and adolescents with autism spectrum disorders. Forty-five youths were randomly assigned to two 8-week acute phases in a double-blind crossover study. Low-dose liquid fluoxetine (mean dosage = 9.9 mg/day) was superior to placebo in reducing repetitive behaviors (Hollander et al. 2005).

In an open study of fluoxetine (dosage range = 20 mg every other day to 80 mg/day) in 23 patients (ages 7–28 years) with autistic disorder, 15 patients (65%) experienced significant clinical global improvement (Cook et al. 1992). The most common side effects were restlessness, hyperactivity, agitation, decreased appetite, and insomnia. Case reports and a retrospective chart review of fluoxetine treatment for youths with autistic disorder reported improvements in irritability, stereotypies, and inappropriate speech (Fatemi et al. 1998; Ghaziuddin et al. 1991; Todd 1991).

Fluvoxamine

A double-blind, placebo-controlled study of fluvoxamine treatment (mean dosage = 106.9 mg/day) in 34 children and adolescents with autistic disorder did not find significant clinical improvement with fluvoxamine (McDougle et al. 2000a).

Sertraline

Open-label sertraline (dosage range = 25–50 mg/day) was administered to nine children with autistic disorder (Steingard et al. 1997). Eight of the nine patients showed clinically significant improvement in ability to tolerate changes in their routine or environment without displaying symptoms of anxiety,

irritability, or agitation. Clinical response tended to occur in 2–8 weeks. In two cases, behavioral worsening was observed when the dosage was raised to 75 mg/day.

Citalopram

Seventeen children with autistic spectrum disorders were treated with citalopram for at least 2 months (Couturier and Nicolson 2002). Ten children (59%) were judged to be much or very much improved on measures of aggression, anxiety, and stereotypies. Common adverse side effects were insomnia and agitation.

Paroxetine

A child with autistic disorder who received paroxetine (up to 10 mg/day) showed a significant reduction in preoccupations and temper tantrums within 6 weeks of treatment initiation (Posey et al. 1999). Snead et al. (1994) described a case of an adolescent with autistic disorder whose symptom of self-injurious behavior resolved within 2 weeks of treatment initiation with paroxetine (20 mg/day).

Escitalopram

In a 10-week open-label study, 28 youths (ages 6–17 years) with pervasive developmental disorder received escitalopram. There was significant improvement in irritability and clinical global functioning. Twenty-five percent of youths responded at escitalopram daily doses less than 10 mg, and 36% of youths responded at doses greater than or equal to 10 mg (Owley et al. 2005).

Other Antidepressants

Clomipramine

The results of controlled trials with clomipramine in the treatment of autistic disorder have yielded mixed results. Clomipramine and haloperidol were compared in a placebo-controlled crossover study for 7 weeks with active treatment (Remington et al. 2001). Thirty-six patients (ages 10–36 years) with autistic disorder were randomly assigned to clomipramine (mean dosage = 128.4 mg/day; range = 100–150 mg/day), haloperidol (mean dosage = 1.3 mg/day; range = 1–1.5 mg), or placebo. A significant advantage for haloperidol was found on global measures of autistic symptom severity and on specific measures of irritability and hyperactivity. Clomipramine was comparable to haloperidol only in patients who were able to complete a full therapeutic trial. However, significantly fewer patients receiving clomipramine versus haloperidol were able to complete the trial (37.5% vs. 69.7%, respectively) for reasons related to inefficacy, side effects, or behavioral problems.

Clomipramine was compared with desipramine for the treatment of autistic disorder in a double-blind crossover study with a sample of 30 patients ranging from 6 to 23 years of age (Gordon et al. 1993). Clomipramine was significantly superior to both desipramine and placebo on ratings of autistic symptoms, including stereotypies, anger, and compulsive ritualized behaviors. No differences were found between desipramine and placebo. One patient had a grand mal seizure during the second week of clomipramine therapy. Clomipramine dosage reduction was necessary in two patients because of QT interval prolongation in one case and severe tachycardia in the other. Increased irritability, temper outbursts, and aggression occurred in 8 of the 12 subjects receiving desipramine.

Mirtazapine

In an open-label study of mirtazapine (dosage range = 7.5–45 mg/day; mean = 30.3 mg/day) in 26 patients (ages 3–23 years) with pervasive developmental disorders, 9 patients (34.6%) were judged much or very much improved in symptoms of aggression, self-injury, irritability, hyperactivity, anxiety, depression, and insomnia (Posey et al. 2001). Mirtazapine did not improve symptoms of social or communication impairment. Common side effects included increased appetite, irritability, and transient sedation.

Venlafaxine

The effectiveness of venlafaxine was assessed in an open retrospective study of 10 patients (ages 3–21 years) with pervasive developmental disorders (Hollander et al. 2000). Six of 10 patients who received venlafaxine (mean dosage = 24.4 mg/day; range = 6.25–50 mg/day) over an average of 5 months were much or very much improved. Improvements were shown in repetitive behaviors, restricted interests, social deficits, communication and language function, inattention, and hyperactivity. Side effects of venlafaxine included behavioral activation, nausea, inattention, and polyuria.

Mood Stabilizers

Lamotrigine

Twenty-eight children (ages 3–11 years) with autistic disorder participated in a double-blind, placebo-controlled study of lamotrigine (mean maintenance dosage = 5 mg/kg/day) for a 12-week study period (Belsito et al. 2001). There were no significant differences between the lamotrigine and placebo groups on severity of behavioral symptoms. Insomnia and hyperactivity were the most frequently reported side effects. No children in the study were withdrawn because of rash.

Lithium

Case studies have reported the effectiveness of lithium in improving manic-like symptoms in children with autism (Kerbeshian et al. 1987; Shafey 1986; Steingard and Biederman 1987).

Anxiolytics

Buspirone

In a 6- to 8-week open trial, 22 children and adolescents with pervasive developmental disorders or autistic disorder were treated with buspirone (dosage range = 15–45 mg/day) (Buitelaar et al. 1998). Sixteen patients (73%) showed moderate to marked improvement in anxiety and irritability symptoms. In a 4-week open trial comparing buspirone with fenfluramine or methylphenidate in children with autistic disorder, two of three children who received buspirone showed improvement in hyperactivity (Realmuto et al. 1989). One patient who received fenfluramine had a slight decrease in hyperactivity. Behavioral deterioration was found in one of two patients treated with methylphenidate.

Other Agents

Flumazenil

One of two children who received flumazenil (a benzodiazepine antagonist) showed a mild increase in interpersonal engagement (Wray et al. 2000). No adverse effects were seen in either child.

Naltrexone

Double-blind, placebo-controlled trials of naltrexone in the treatment of children with autistic disorder have reported modest improvement of symptoms, including reductions in autistic symptomatology (Scifo et al. 1996); decreased self-injurious behavior, improved socialization, and increased attentiveness and communication (Leboyer et al. 1992); improved socialization, decreased withdrawal, increased proximity seeking, increased eye contact, increased attentiveness, and decreased restlessness and affective lability (Leboyer et al. 1990); decreased irritability (Willemsen-Swinkels et al. 1995); decreased hyperactivity and irritability (Willemsen-Swinkels et al. 1996); decreased restlessness and hyperactivity (Kolmen et al. 1995); decreased self-injury (Barrett et al. 1989); decreased hyperactivity (Campbell et al. 1993); and global improvement as assessed by teacher ratings (Kolmen et al. 1997). Dosage ranges of naltrexone were 0.5–1.5 mg/kg in these

studies. There were no significant changes in cardiovascular parameters of heart rate or systolic blood pressure for children with autism treated with naltrexone (Herman et al. 1993).

In other controlled trials, naltrexone demonstrated no superiority over placebo in producing beneficial changes in social behavior (Willemsen-Swinkels et al. 1995), social and stereotypic behavior (Willemsen-Swinkels et al. 1996), social behavior and activity level (Bouvard et al. 1995), discrimination learning (Campbell et al. 1993), and communication (Feldman et al. 1999).

During 6-month continuation treatment for naltrexone-responsive children with autism, the hyperactivity-reducing effect of naltrexone was maintained (Willemsen-Swinkels et al. 1999). However, no additional gains in social interaction, communication, or stereotypic behaviors were observed after the 4-week acute phase. Moreover, parents did not request to continue treatment with naltrexone for their autistic children. These researchers therefore did not advocate the routine use of naltrexone for children with autism.

Clonidine

A double-blind, placebo-controlled crossover study with transdermal clonidine (0.005 mg/kg/day or placebo by a weekly transdermal patch) in nine patients (ages 5–33 years) with autistic disorder was conducted for a total 8-week active period (Fankhauser et al. 1992). Significant improvement with clonidine, compared with placebo, was found on measures of social relationship, affectual responses, and sensory responses. In a double-blind, placebo-controlled crossover trial of clonidine in eight children with autistic disorder, clonidine was found to be modestly effective in reducing irritability and hyperactivity (Jaselskis et al. 1992).

Methylphenidate

There have been two small double-blind, placebo-controlled crossover studies of methylphenidate for the treatment of autistic disorder in children ranging in age from 5 to 11 years. In a study that included 10 children, a modest but statistically significant improvement in hyperactivity was found with methylphenidate treatment, compared with placebo (Quintana et al. 1995). No significant side effects, such as worsening of behavior or of stereotypic movements, were observed. In a study that included 13 children, 6 patients had a significant decrease in hyperactivity, stereotypies, and inappropriate speech (Handen et al. 2000). However, there were no changes found on the Child Autism Rating Scale. Significant adverse side effects occurred in some children and included social withdrawal and irritability, particularly at a methylphenidate dosage of 0.6 mg/kg/day.

Fenfluramine

Fenfluramine, a serotonin agonist, has been studied in autism. It was marketed as an anti-obesity agent but was withdrawn from the market because of pulmonary hypertension when used in combination with phentermine.

Following the report of significant clinical improvement and an increase in the IQs of three boys who received fenfluramine (E. Geller et al. 1982), a number of double-blind, placebo-controlled studies were conducted to assess the efficacy and safety of fenfluramine in the treatment of children with autism. The results of these studies have been mixed, with modest improvements in autistic symptoms found in a few studies.

Children who received fenfluramine, compared with placebo, were reported to have decreased hyperactivity, decreased stereotypies, increased eye contact, increased socialization, and increased use of appropriate language (Ritvo et al. 1983); decreased motor activity, decreased distractibility, and improved mood (August et al. 1984); increased social awareness, eye contact, and attention to schoolwork (Ritvo et al. 1984); increased IQ, increased communication, and increased socialization (Ritvo et al. 1986); decreased respiratory stereotypies (Gastaut et al. 1987); reduction in motor

activity, anxiety, mood disturbance, and distractibility (Barthelemy et al. 1989); improved attention span and activity level (Groden et al. 1987); increased language and awareness of environment in children with IQs above 40 (Stubbs et al. 1986); and decreased activity level, increased attention, and decreased hyperactivity (August et al. 1985). Open studies with fenfluramine reported improvement in relatedness, hyperactivity, irritability, and aggressiveness (Campbell et al. 1986) and improved communication and social awareness (Klykylo et al. 1985).

However, numerous reports of controlled trials failed to show significant superiority of fenfluramine relative to placebo in the treatment of children with autistic disorder (Beeghly et al. 1987; Beisler et al. 1986; Campbell et al. 1988b; Coggins et al. 1988; Ekman et al. 1989; Ho et al. 1986; Kohler et al. 1987; Leventhal et al. 1993; Ross et al. 1987; Sherman et al. 1989; Stern et al. 1990; Yarbrough et al. 1987). The average dose of fenfluramine was 1.5 mg/day in these studies.

In a review of the literature, Aman and Kern (1989) concluded that there was no evidence that IQ was increased by fenfluramine. Fenfluramine may enhance social relatedness, reduce stereotypic behavior, lessen overactivity, and improve attention span in some children, although the results are inconsistent. In another review, du Verglas et al. (1988) concluded that fenfluramine may have positive effects in reducing hyperactivity and stereotypic behaviors in 33% of children and noted that the best responders were children with the highest baseline IQs.

There had been concern about the untoward effects of fenfluramine in children with autism. Realmuto et al. (1986) described listlessness, food refusal, and stomach upset in the initial phase of treatment, followed by irritability, agitation, and crying with continued medication use. Decreased appetite, lethargy, irritability, and behavioral regression were also reported with fenfluramine use (Piggott et al. 1986). In a 2-year follow-up of autistic children treated with fenfluramine, reasons for discontinuing the medication included development of tolerance, appetite and weight changes, and the need for other interventions, particularly other psychotropic medications (Varley and Holm 1990). Significant concern had also been raised about possible neurotoxicity with the use of fenfluramine in children, based on studies of the neurotoxic effects of fenfluramine in animals (Schuster et al. 1986).

Famotidine

The efficacy of famotidine, a histamine$_2$ receptor antagonist, was assessed in a randomized, double-blind, placebo-controlled crossover study in nine children (ages 3–8 years) with a diagnosis of pervasive developmental disorder (Linday et al. 2001). The maximum daily dose of famotidine was 100 mg (2 mg/kg/day). Four of nine children (44%) randomly assigned to famotidine showed increased social interaction and affection. Children with marked stereotypy did not respond.

Amantadine

Thirty-nine children and adolescents (ages 5–19 years) with autistic disorder were randomly assigned in a 9-week double-blind, placebo-controlled trial to amantadine (5 mg/kg/day) or placebo (King et al. 2001). Parent ratings did not demonstrate a statistically significant change in irritability and hyperactivity, with a mean placebo response rate of 37% versus 47% for amantadine. However, clinician ratings of improvement in behavioral changes of hyperactivity and inappropriate speech were significantly higher in the amantadine group than in the placebo group. Overall clinical functioning was rated higher in the amantadine group than in the placebo group (53% improved vs. 25% improved, respectively). The most common side effects were insomnia and somnolence.

Amisulpride

Nine children (ages 4–13 years) with autistic disorder participated in a randomized, double-blind crossover trial of amisulpride (1.5 mg/kg/day) and bromocriptine (0.15–0.20 mg/kg/day) for two consecutive 8-week treatment periods (Dollfus et al. 1992). Neither amisulpride nor bromocriptine showed a statistically significant effect on global autism scores. However, the two agents differed in

their effects on specific autistic symptoms, with amisulpride having a more positive effect on behavioral inhibition and withdrawal symptomatology and bromocriptine having a more positive effect on motor hyperactivity and attention symptoms. The most common side effects were insomnia and anorexia for amisulpride and bromocriptine, respectively. Amisulpride is not available in the United States or Canada.

Sulpiride

Sulpiride (up to 400 mg/day) was reported to significantly reduce abnormal speech and withdrawal in a teenager with autistic disorder (Scott and Eames 1988). Sulpiride is not available in the United States or Canada.

Secretin

Following the report of marked improvement in socialization and communication skills in three children with autism who had received secretin during an upper endoscopy (Horvath et al. 1998), there was a flurry of media reports about the success of this neuropeptide hormone. It is estimated that approximately 2,500 children have received secretin injections for the treatment of autism (Kastner 1998). However, randomized, double-blind, placebo-controlled trials of single-dose intravenous secretin for the treatment of children with autism have produced no evidence that secretin is effective for the treatment of autism or pervasive developmental disorder in 174 children and adolescents who participated in the studies. There have been no significant changes in parents' perceptions of autistic behaviors or language skills (Coniglio et al. 2001), no improvement in either primary or secondary features of autism (Sandler et al. 1999), and no change in social and communication skills (Owley et al. 2001).

The efficacy of repeated doses of secretin in the treatment of autism was assessed in a double-blind, placebo-controlled trial in 64 children (ages 2–7 years) who received two doses of secretin 6 weeks apart (Roberts et al. 2001). No differences between the secretin and placebo groups were found on measures of language, cognition, or autistic symptomatology. Similarly, in a controlled study of 12 children with autism, there were no significant differences between secretin and placebo groups on language or social assessments (Corbett et al. 2001).

Clinical Recommendations for Autistic Disorder and Other Pervasive Developmental Disorders

There is no evidence that pharmacotherapy is effective in treating the core social and communication deficits in autistic disorder. However, medications have been shown to be useful in treating associated symptoms, such as hyperactivity, inattention, stereotypies, self-injurious behavior, tantrums, aggression, mood lability, and anxiety. Antipsychotics may decrease withdrawal, stereotypies, and aggression and may facilitate learning. To date, the most data available support the use of risperidone for treating irritability, aggression, self-injurious behavior, temper tantrums, and mood lability associated with autistic disorder in children and adolescents. Serotonin reuptake inhibitors and other antidepressants have been shown to reduce compulsions, anxiety, and depression in children with autism. In some cases, naltrexone may reduce hyperactivity, irritability, and self-injurious behavior. Stimulants may increase attention span and reduce hyperactivity. Given concerns about the potential neurotoxicity and limited effectiveness of fenfluramine, this agent should be used with extreme caution in children with autism. Secretin is not recommended for use because it has no established efficacy.

There are limited data on the long-term use of pharmacotherapy in children with autism. After receiving an intermediate-length (4–6 months) course of treatment with risperidone, children withdrawn from the medication through placebo substitution had high relapse rates (Research Units on Pediatric Psychopharmacology Autism Network et al. 2005; Troost et al. 2005). Therefore,

clinicians must weigh the risk–benefit ratio of maintenance medication treatment in this population and carefully monitor children for side effects.

APPENDIX

Psychotropic Medications Commonly Prescribed for Children and Adolescents

This Appendix describes common classes of psychotropic medications used to treat children and adolescents. Dosages, common side effects, and monitoring schedules are presented for each medication class.

Antidepressants

Dosage and Monitoring

The starting and target doses of antidepressants for children and adolescents are listed in Table 63–1.

TABLE 63–1. Clinical use of antidepressants in children and adolescents

	Typical starting dose (mg)		
Medication	**Child**	**Adolescent**	**Target dose (mg/day)**
Citalopram	5–10	10	20–40
Escitalopram	5	10	10–20
Fluoxetine	5–10	10	20–40
Paroxetine	5–10	10	20–40
Sertraline	25	50	100–200
Mirtazapine	15	15	30–45
Venlafaxine	37.5	37.5	150–225
Bupropion	50 bid	50 bid	100–200

Premedication laboratories include complete blood count, blood chemistries, and liver function tests. Blood pressure should be monitored during dose titration with venlafaxine.

The FDA has issued the following black box warning, which applies to all antidepressants (U.S. Food

and Drug Administration 2007):

> Antidepressants increased the risk compared to placebo of suicidal thinking and behavior (suicidality) in children, adolescents, and young adults in short-term studies of major depressive disorder (MDD) and other psychiatric disorders. Anyone considering the use of [Name of Antidepressant] or any other antidepressant in a child, adolescent, or young adult must balance this risk with the clinical need. Short-term studies did not show an increase in the risk of suicidality with antidepressants compared with placebo in adults beyond age 24 years; there was a reduction in risk with antidepressants compared with placebo in adults ages 65 years and older. Depression and certain other psychiatric disorders are themselves associated with increases in the risk of suicide. Patients of all ages who are started on antidepressant therapy should be monitored appropriately and observed closely for clinical worsening, suicidality, or unusual changes in behavior. Families and caregivers should be advised of the need for close observation and communication with the prescriber.

Side Effects

Common side effects of SSRIs are headache, nausea, abdominal pain, dry mouth, insomnia, and somnolence (Emslie et al. 2002; Keller et al. 2001; Wagner et al. 2003a, 2004b, 2006a). Potential serious adverse events include serotonin syndrome, extrapyramidal symptoms (tics, myoclonus), amotivational syndrome, and increased bleeding (Hammerness et al. 2006). A major advantage of SSRIs is their safety in overdose (Barbey and Roose 1998).

Common side effects of mirtazapine are somnolence, increased appetite, weight gain, dizziness, dry mouth, and constipation (Green 2001).

Common side effects of venlafaxine include anorexia, abdominal pain, insomnia, somnolence, dizziness, dry mouth, increased sweating and nervousness, and elevated blood pressure with dose increase (Emslie et al. 2007a; Green 2001).

Common side effects of bupropion are headache, nausea, rash, irritability, drowsiness, fatigue, and anorexia (Barrickman et al. 1995; Conners et al. 1996; Daviss et al. 2001). Bupropion is contraindicated in children with seizure disorders, since it may lower the seizure threshold.

Atomoxetine

Dosage and Monitoring

Atomoxetine can be given in the late afternoon or evening, whereas stimulants generally cannot; atomoxetine may have less pronounced effects on appetite and sleep than stimulants, though it may produce relatively more nausea or sedation. Gastrointestinal distress can be minimized by taking the medication after a meal. In children and young adolescents, atomoxetine is initiated at a dosage of 0.3 mg/kg/day and titrated over 1–3 weeks to a maximum dosage of 1.2–1.8 mg/kg/day (Kratochvil et al. 2003). Adults or adult-sized adolescents should be started on atomoxetine 40 mg daily and titrated to 80–100 mg/day of atomoxetine over 1–3 weeks, if needed (Kratochvil et al. 2003). Atomoxetine's labeling recommends both once-daily and twice-daily dosing, although its elimination half-life of 5 hours (as well as clinical experience) suggests that twice-daily dosing (early A.M. and early P.M) is more effective and less prone to cause side effects. Michelson et al. (2002) showed that while atomoxetine was superior to placebo at week 1 of the trial, its greatest effects were observed at week 6, suggesting that patients should be maintained at the full therapeutic dose for at least several weeks in order to observe the drug's full effects.

Side Effects

Side effects of atomoxetine that occurred more often than placebo in clinical trials included gastrointestinal distress, sedation, and decreased appetite. These can generally be managed by

dosage adjustment and often attenuate with time. On December 17, 2004, the FDA required that a warning be added to atomoxetine due to reports of two patients (an adult and child) who developed severe liver disease (U.S. Food and Drug Administration 2006a). Both patients recovered. The FDA has also issued an alert regarding suicidal thinking with atomoxetine in children and adolescents (U.S. Food and Drug Administration 2005). A black box warning is included in the package insert. In 12 controlled trials involving 1,357 patients on atomoxetine and 851 on placebo, the average risk of suicidal thinking was 4 per 1,000 in the atomoxetine-treated group versus none in the placebo group.

Atypical Antipsychotics

Dosage and Monitoring

Typical starting and target dosages of atypical antipsychotics are listed in Table 63–2.

TABLE 63–2. Clinical use of atypical antipsychotics in children and adolescents

Medication	Typical starting dose (mg)	Target dose (mg/day)
Clozapine	25 twice daily	200–400
Olanzapine	2.5 twice daily	10–20
Quetiapine	50 twice daily	400–600
Risperidone	0.25 twice daily	1–2
Ziprasidone	20 twice daily	80–120
Aripiprazole	2.5–5.0 at bedtime	10–25

Source. DelBello and Kowatch 2006.

Premedication laboratories include complete blood count, blood chemistries, and liver function tests. In addition, the American Diabetes Association et al. (2004) recommendations should be followed. These include baseline body mass index (BMI), waist circumference, blood pressure, and fasting glucose and lipid panels. BMI should be followed monthly for 3 months, and then measured quarterly. Blood pressure, fasting glucose, and lipid panels should be followed up at 3 months and then yearly. Monitoring should also be done for extrapyramidal side effects.

Side Effects

Side effects of atypical antipsychotics include weight gain, dyslipidemia, insulin resistance and diabetes, hyperprolactinemia, extrapyramidal side effects and akathisia, QTc prolongation, sedation, liver toxicity, neutropenia, and neuroleptic malignant syndrome. Clozapine has also been associated with seizures, agranulocytosis, and myocarditis (Correll et al. 2006).

Clonidine

Dosage and Monitoring

Clonidine is initiated at 0.05 mg/day, with dose increases of 0.05 mg every 3 days. Typical dosages for ADHD are in the range of total 0.15–0.3 mg/day (on a three-times-per-day schedule). Transdermal clonidine delivers doses of 0.1, 0.2, or 0.3 mg/day. During initial treatment, a temporary worsening of motor and phonic tics in Tourette's syndrome may occur, which usually resolves within 2–4 weeks. Clonidine should be tapered by 0.05 mg/day upon discontinuation (Hunt et al. 1990).

Given the reports of adverse cardiovascular side effects in children taking clonidine, recommendations have been made regarding cardiovascular monitoring (Cantwell et al. 1997). Pulse and blood pressure should be measured at baseline, weekly during titration of dose, and every 4–6 weeks during maintenance treatment. ECGs should be obtained at baseline and after the maximal dose of clonidine

is achieved. Abrupt discontinuation of clonidine is not recommended, because it increases the risk of adverse cardiovascular side effects, particularly hypertension.

Side Effects

Common side effects of clonidine in children are sedation, depression, irritability, hypotension, sleep disturbance, dry mouth, and dizziness. Skin irritation and erythema are common with the clonidine patch (Connor et al. 1999; Hunt et al. 1990). Rebound tachycardia and hypertension may occur if clonidine is abruptly discontinued, particularly after chronic use (Popper 2000).

Safety concerns have been raised about the combination of clonidine and methylphenidate, following the report of four cases of sudden death in children on this medication combination (Cantwell et al. 1997; Fenichel 1995). Swanson et al. (1995) described two types of clonidine-related cardiovascular side effects. In one type, fatigue and sedation were associated with a decrease in pulse and blood pressure and changes in ECG. In the other, tachycardia and tachypnea occurred, which led to anxiety, fever, and changes in mental status. Adverse cardiovascular side effects, including bradycardia and depressed level of consciousness, have been reported with clonidine overdose in children (Kappagoda et al. 1998). However, in a retrospective study of 42 children treated with clonidine alone or clonidine plus stimulants, no systematic effects were found on ECG parameters of pulse rate or QTc intervals (Kofoed et al. 1999).

Guanfacine

Dosage and Monitoring

Guanfacine is initiated at a daily dose of 0.5 mg, with an upward titration of 0.5 mg every 3 days, based on clinical response and tolerability, to a maximum daily dose of 4 mg (Hunt et al. 1995).

Pulse and blood pressure should be monitored during guanfacine treatment. Guanfacine should be tapered over a 4-day period upon discontinuation.

Side Effects

Common side effects of guanfacine in children are sedation, fatigue, headache, dizziness, stomachache, and decreased appetite (Chappell et al. 1995b; Hunt et al. 1995; Melmed et al. 2006; Scahill et al. 2001). Rebound hypertension, nervousness, and anxiety may occur if guanfacine is abruptly discontinued (Green 2001).

Mood Stabilizers

Dosage and Monitoring

The starting dose and target doses and therapeutic serum levels of mood stabilizers are listed in Table 63–3.

TABLE 63–3. Clinical use of mood stabilizers in children and adolescents

Medication	Typical starting dose (mg)	Target dose	Therapeutic serum level
Carbamazepine	7 mg/kg/day	Based on response and serum level	8–11 μg/L
Lamotrigine	12.5 mg once daily	Based on response	NA
Lithium	25 mg/kg/g (2–3 daily doses)	30 mg/kg/day (2–3 daily doses)	0.8–1.2 mEq/L

Medication	Typical starting dose (mg)	Target dose	Therapeutic serum level
Oxcarbazepine	150 mg twice daily	20–29 kg (900 mg/day) 30–39 kg (1,200 mg/day) >39 kg (1,800 mg/day)	NA
Topiramate	25 mg once daily	100–400 mg/day	NA
Valproic acid, divalproex sodium	20 mg/kg/day (2 daily doses)	20 mg/kg/day (2–3 daily doses)	90–120 μg/mL

Source. DelBello and Kowatch 2006.

Premedication laboratories in general include complete blood count, liver function tests, and pregnancy test (for females).

For lithium, baseline thyroid function tests, electrolytes, urinalysis, blood urea nitrogen, creatinine, and serum calcium should also be obtained. Lithium levels, renal function, thyroid function, and urinalysis should be monitored every 3–6 months.

For divalproex, drug serum levels, complete blood count, and liver function tests should be monitored every 3–6 months. Given concerns about a possible relationship between divalproex and polycystic ovarian syndrome (PCOS) (Rasgon 2004), female adolescents taking divalproex should be monitored for signs of PCOS, including menstrual abnormalities, weight gain, acne, and hirsutism (DelBello and Kowatch 2006; McClellan et al. 2007). Parents and their female adolescents should be apprised about this possible association prior to initiating medication.

For oxcarbazepine, children should be monitored for hyponatremia.

Side Effects

Common side effects of lithium in children and adolescents include hypothyroidism, nausea, polyuria, polydypsia, acne, tremor, and weight gain (DelBello and Kowatch 2006).

Common side effects of divalproex in children and adolescents include weight gain, nausea, sedation, and tremor (DelBello and Kowatch 2006). Concern has been raised about a possible association between divalproex and PCOS (Rasgon 2004). Other potential side effects of concern are hepatic failure, pancreatitis, thrombocytopenia, behavioral deterioration, and hair loss (Davanzo and McCracken 2000; Green 2001).

Side effects of topiramate include decreased appetite, weight loss, nausea, diarrhea, paresthesias, somnolence, and word-finding difficulties (DelBello and Kowatch 2006; DelBello et al. 2005).

Side effects of oxcarbazepine in children include dizziness, nausea, somnolence, diplopia, fatigue, and rash (Wagner et al. 2006b). Hyponatremia is also a side effect of oxcarbazepine.

Common side effects of lamotrigine in children include ataxia, nausea, vomiting, and constipation. Of concern is the incidence of serious rash, including Stevens-Johnson syndrome, in pediatric patients reported to be 1%. This high incidence of serious rash may be attributable to the prior use of high doses of lamotrigine with concomitant divalproex (Messenheimer et al. 1998). The current dosing guidelines may reduce this rash incidence in pediatric patients.

Psychostimulants

Dosage and Monitoring

The American Academy of Child and Adolescent Psychiatry (2007) recently revised its parameters for the diagnosis and treatment of attention-deficit/hyperactivity disorder ADHD). A wide variety of stimulant preparations are available; Table 63–4 describes their use in clinical practice. Each stimulant

has a maximum dose suggested by the U.S. Food and Drug Administration (FDA)–approved package insert, but higher off-label doses are commonly used with careful monitoring. In terms of safety monitoring, pulse, blood pressure, weight, and height should be obtained at baseline and at least annually. No laboratory measures or electrocardiogram (ECG) monitoring is required.

TABLE 63–4. Clinical use of psychostimulants in children and adolescents

Medication	Dosage form	Typical starting dose	FDA max/day	Off-label max/day
Amphetamine preparations				
Adderall	5, 7.5, 10, 12.5, 15, 20, 30 mg	3–5 yr: 2.5 mg qd ≥6 yr: 5 mg qd–bid	40 mg	>50 kg: 60 mg
Dexedrine	5 mg	3–5 yr: 2.5 mg qd ≥6 yr: 5 mg qd-bid	40 mg	>50 kg: 60 mg
DextroStat	5, 10 mg	3–5 yr: 2.5 mg qd ≥6 yr: 5 mg qd–bid	40 mg	>50 kg: 60 mg
Dexedrine Spansule	5, 10, 15 mg	≥6 yr: 5–10 mg qd–bid	40 mg	>50 kg: 60 mg
Adderall XR	5, 10, 15, 20, 25, 30 mg	≥6 yr: 10 mg qd	30 mg	>50 kg: 60 mg
Vyvanse	30, 50, 70 mg	30 mg qd	70 mg	Not determined
Methylphenidate preparations				
Focalin	2.5, 5, 10 mg	2.5 mg bid	20 mg	50 mg
Focalin XR	5, 10, 15, 20 mg	5 mg q A.M.	30 mg	50 mg
Methylin	5, 10, 20 mg	5 mg bid	60 mg	>50 kg: 100 mg
Metadate ER	10, 20 mg	10 mg q A.M.	60 mg	>50 kg: 100 mg
Methylin ER	10, 20 mg	10 mg q A.M.	60 mg	>50 kg: 100 mg
Ritalin SR	20 mg	10 mg q A.M.	60 mg	>50 kg: 100 mg
Metadate CD	10, 20, 30, 40, 50, 60 mg	20 mg q A.M.	60 mg	>50 kg: 100 mg
Ritalin LA	20, 30, 40 mg	20 mg q A.M.	60 mg	Not yet known
Concerta	18, 27, 36, 54 mg	18 mg q A.M.	72 mg	108 mg
Daytrana patch	10-, 15-, 20-, 30-mg patches	Begin with 10-mg patch qd, then titrate up by patch strength	30 mg	Not yet known

Note. qd = once daily; bid = twice daily; q A.M. = every morning.

Side Effects

Common side effects of psychostimulants are insomnia, diminished appetite, weight loss, irritability, abdominal pain, and headaches (American Academy of Child and Adolescent Psychiatry 2007). Rebound symptoms of worsening behavior may occur when the effects of the short-acting psychostimulants dissipate. Switching to sustained-release or longer-acting psychostimulants may ameliorate rebound symptoms.

There is no evidence that psychostimulants increase substance abuse in youths with ADHD. On the

contrary, youths with ADHD who were treated with psychostimulants were at less risk for developing substance abuse than those youths with ADHD who did not receive stimulants (Wilens et al. 2003a). Motor tics may develop during treatment with stimulants, but one study reported no increase in tics for children with or without preexisting tics who received typical clinical doses of methylphenidate compared with placebo (Law and Schachar 1999).

The FDA and its Pediatric Advisory Committee have reviewed data regarding psychiatric adverse events to stimulant medication (U.S. Food and Drug Administration 2006b). Data from both controlled trials and post-marketing safety data from sponsors and the FDA Adverse Events Reporting System (AERS), also referred to as MedWatch, were reviewed. For most of the agents, these events were slightly more common in the active-drug group relative to placebo in the controlled trials, but these differences did not reach statistical significance (Mosholder 2006). Postmarketing safety data were also reviewed for reports of mania/psychotic symptoms, aggression, and suicidality (Gelperin 2006). Rare events of suicidal thoughts, manic-like activation, or psychosis were reported. At the time, the Pediatric Advisory Committee did not recommend a black box warning regarding psychiatric adverse events but did suggest clarifying labeling regarding these phenomena. No changes to the stimulant medication labeling were suggested regarding suicide or suicidal ideation.

There have been rare reports of sudden death in patients taking stimulant medication The FDA has record of 20 cases of sudden death with amphetamine or dextroamphetamine (14 children, 6 adults), while there were 14 pediatric and 4 adult cases of sudden death with methylphenidate (Villalaba 2006). It is important to note that the rate of sudden death in the general pediatric population has been estimated at 1.3–8.5 per 100,000 patient-years (Liberthson 1996). The rate of sudden death among those with a history of congenital heart disease can be as high as 6% by age 20 years (Liberthson 1996). Villalaba (2006) estimated the rate of sudden death in treated ADHD children for the exposure period January 1, 1992, to December 31, 2004, to be 0.2 per 100,000 patient-years for methylphenidate, 0.3 per 100,000 patient-years for amphetamine, and 0.5 per 100,000 patient-years for atomoxetine (the differences between the agents are not clinically meaningful). Thus, the rate of sudden death of children on ADHD medications does not appear to exceed the base rate of sudden death in the general population; therefore, cardiac monitoring of healthy children during treatment with stimulants is not required. Children with preexisting heart disease (or significant symptoms suggesting the condition) should obtain a cardiology consultation prior to starting a stimulant.

Poulton (2005) reviewed growth data and concluded that stimulant treatment may be associated with a reduction in expected height gain, at least in the first 1–3 years of treatment. The National Institute of Mental Health (NIMH) Multimodal Treatment of ADHD (MTA) study showed reduced growth rates in ADHD patients after 2 years of stimulant treatment compared with patients who received no medication (MTA Cooperative Group 2004), and these deficits persisted at 36 months (MTA Cooperative Group 2007). The PATS study followed a group of 140 preschoolers who received methylphenidate for up to a year for ADHD (Swanson et al. 2006b). The subjects had less than expected mean gains in height (–1.38 cm) and weight (–1.3 kg). Charach et al. (2006) found that higher doses of stimulant correlated with reduced gains in height and weight and that the effect did not become significant until the dose in methylphenidate equivalents was >2.5 mg/kg/day for 4 years. Pliszka et al. (2006b) did not find that children with ADHD treated with monotherapy with either amphetamine or methylphenidate showed any failure to achieve expected height; furthermore the two stimulant classes did not have any differential effect on height, but amphetamine had somewhat greater effects on weight than methylphenidate. The subjects in this study had drug holidays averaging 31% of time during their treatment course, which may have contributed to the lack of effect of the stimulant on height.

In assessing for clinically significant growth reduction, it is recommended to use serial plotting of height and weight on growth charts labeled with lines showing the major percentiles (5th, 10th, 25th,

50th, 75th, 90th, and 95th) (Mei et al. 2004). This should occur one to two times per year, and more frequently if practical. If the patient has a change in height or weight that crosses 2 percentile lines, this suggests an aberrant growth trajectory. In these cases, a drug holiday should be considered, if return of symptoms during weekends or summers does not lead to marked impairment of functioning. The clinician should also consider switching the patient to another ADHD medication. It is important for the clinician to carefully balance the benefits of medication treatment with the risks of small reductions in height gain, which as of yet have not been shown to be related to reductions in adult height (Gittelman-Klein and Mannuzza 1988; Kramer et al. 2000; Weiss and Hechtman 2003).

Chapter 64. Psychopharmacology During Pregnancy and Lactation

PSYCHOPHARMACOLOGY DURING PREGNANCY AND LACTATION: INTRODUCTION

The management of mental illness during pregnancy and lactation represents a unique and complex clinical situation involving a minimum of two concomitant medical conditions (i.e., pregnancy and a psychiatric disorder) and also demanding consideration of the welfare of at least two patients (i.e., mother and child), not to mention the potential impact of maternal illness on the family at large. The American College of Obstetricians and Gynecologists Practice Bulletin on the use of psychotropic medications during pregnancy and lactation acknowledges the potential adverse impact of untreated or inadequately treated maternal mental illness (American College of Obstetricians and Gynecologists 2007).

Given the high incidence of psychiatric disorders among women during the childbearing years, the increasing proportion of women who plan to nurse, and the introduction of new psychotropic medications that are less likely to interfere with female reproductive physiology (e.g., second-generation antipsychotics [SGAs]), clinicians will be more frequently confronted with this complex dilemma. The most common scenarios in which physicians provide care for a patient with a mental disorder while she is pregnant or nursing include the following:

- Preconception consultation with a patient who wishes to have a baby but who has a history of a chronic or recurrent psychiatric illness and/or who currently takes one or more psychotropic medications
- Urgent consultation in early pregnancy with a patient who has inadvertently conceived during treatment with one or more psychotropic medications
- Provision of treatment to a patient who is experiencing an exacerbation of a preexisting mental illness during pregnancy or the postpartum, often after having discontinued pharmacological treatment proximate to conception
- Provision of treatment to a patient who is experiencing the onset of a new mental illness during pregnancy or the postpartum
- Formulation of plans during pregnancy to provide prophylactic treatment at some juncture to a patient who is at high risk for postpartum mental illness

Despite rapid advances, the extant literature regarding psychotropic therapy during pregnancy and lactation remains hampered by a cadre of confounds that preclude definitive treatment guidelines. Existing studies lack methodological consistency and are often without the requisite sample size or study design necessary to establish a significant causal relation for deleterious effects of psychotropic medications. Specific methodological concerns include 1) limited effort to control for the concomitant effect of maternal illness on obstetrical and infant outcome; 2) limited effort to control for the potentially confounding effects of other nonpsychotropic exposures that might accompany maternal mental illness; 3) failure to provide objective confirmation of purported exposures, with a tacit assumption of full maternal psychotropic compliance and disclosure of other concomitant exposures (e.g., tobacco, alcohol); and 4) widespread reliance on retrospective recall to document exposures and/or outcomes (even in many so-called prospective studies) months or even years after delivery, with a potential for systematic recall bias. As early as 6 months after delivery, maternal retrospective

reports demonstrate systematically biased underreporting of depression and use of nonpsychotropic agents during pregnancy, whereas use of psychotropic agents is accurately reported (Newport et al. 2008b).

The proper assessment of the risk to offspring attributable to psychotropic exposure must consider the baseline frequencies of obstetrical complications and developmental anomalies, the timeline of embryonic and fetal development, the potential risks of exposure to nonpsychotropic medications, and the potential risks associated with untreated maternal psychiatric illness. In the United States, 84.5% of pregnancies result in a live delivery (Kiely 1991; McBride 1972). Recent birth registry data collectively comprising nearly 2.5 million deliveries in New York State and Sweden indicate that 3%–4% of these infants will suffer from major malformations (New York State Department of Health 2005; Swedish Centre for Epidemiology 2004). Most major malformations occur during the embryonic period (i.e., the third through the eighth week of gestation), and most organ systems (with the notable exception of the central nervous system [CNS]) are developed by the conclusion of week 11 (Sadler 1985). Finally, it must be noted that medications are prescribed to up to 80% of pregnant women (Cohen et al. 1989), and more than one-third take a psychotropic medication at some point during pregnancy (Doering and Stewart 1978).

Because clinical experience indicates that the principal goal of both patient and clinician is to minimize potentially harmful offspring exposure, we propose in this chapter a rational model for developing perinatal treatment guidelines that is founded on the shared conviction that minimizing infant exposure to the effects of both maternal illness and maternal treatment is the preeminent objective. We subsequently review the available data regarding pharmacokinetic and pharmacodynamic alterations during pregnancy and lactation and describe the clinical relevance of these data for psychotropic dose management and forecasting of offspring exposure. We then review the available data regarding the potential risks of pharmacotherapy during pregnancy or lactation with specific psychotropic agents from various medication classes, including antidepressants, mood stabilizers, antipsychotics, and anxiolytics. We conclude the chapter with a review of the future directions for perinatal psychiatric research and a discussion of potential modifications of previously suggested treatment guidelines, emphasizing the need for an individualized risk–benefit assessment.

A MODEL FOR TREATMENT GUIDELINES DURING PREGNANCY AND LACTATION: MINIMIZING OFFSPRING EXPOSURE

The clinical management of any medical condition during pregnancy and lactation is one of "relative safety" that must consider the reproductive safety of available therapies, the likelihood of illness relapse or exacerbation in the absence of continued treatment, and the potential impact of untreated maternal illness. Minor ailments, including headaches, nausea, insomnia, and localized infections, are routinely treated during pregnancy with medications that often have limited reproductive safety data. Conversely, women with mental illness are often encouraged to discontinue psychotropic medication during pregnancy and lactation. The underlying desire to avoid offspring psychotropic exposure is laudable; however, such recommendations are often made with limited knowledge of the potential adverse obstetrical effects of maternal mental illness and an assumption that psychotropic medications are poorly represented in the reproductive safety database. Comprehensive treatment guidelines for perinatal psychiatric illness must therefore incorporate an appraisal of the clinical consequences of offspring exposure to both maternal illness and available therapies.

When the clinician conducts a risk–benefit assessment for new or expectant mothers with mental illness, it must first be acknowledged that the possibility of offspring exposure, to either treatment or illness, is always present. Advising a pregnant or breast-feeding patient to discontinue psychotropic medication does not eliminate offspring exposure; it simply exchanges the risks of psychotropic exposure for the risks of untreated maternal illness. A thorough risk–benefit assessment also requires an understanding of the pathways of offspring exposure. In the context of perinatal psychiatric

illness, fetal/neonatal exposure may occur either directly or indirectly (Stowe et al. 2001). *Direct exposure* is imparted by any biological or pharmacological substrate that comes into direct contact with the child. *Indirect exposure* is conferred by the influence of such a substrate on the child's environment.

Direct exposure to psychotropic agents is a given. All psychotropics studied to date cross the placenta (Hendrick et al. 2003b; Newport et al. 2005, 2007; Stowe et al. 1997), are present in amniotic fluid (Hostetter et al. 2000), and are excreted into breast milk (Newport et al. 2002a). Clinicians often assume that liability exists only for those direct exposures to medications that are under their immediate control, but other exposures should engender concern. The fetus and breast-feeding infant are also directly exposed to maternal illness via changes in the hormonal and immunological constituents within the fetomaternal circulation (Wadhwa et al. 1998) and breast milk (Cox et al. 2000). The magnitude and clinical significance of these direct exposures to the substrates of maternal illness remain obscure.

Indirect exposures to illness or treatment are also possible, although less readily apparent. Indirect effects of maternal psychiatric illness on offspring may be mediated by poor maternal compliance with prenatal care, inadequate maternal nutrition, exposure to other prescription or over-the-counter medications or herbal remedies, increased use of alcohol and tobacco, deficits in mother–infant bonding, and disruptions within the family environment. Indirect exposure to psychotropic therapy may be conferred by treatment-emergent side effects (e.g., somnolence, alterations in appetite).

Assessing the risks of offspring exposure to maternal psychiatric illness must consider both the likelihood that an episode of illness will occur and the evidence that the illness may be harmful to the child. The clinician can estimate a patient's likelihood of peripartum recurrence or exacerbation by carefully synthesizing prevalence data from epidemiological studies with evidence from the patient's own history. Gathering comprehensive personal and family psychiatric histories is critical to treatment planning. Patients with frequent episodes of psychiatric illness, a declining course, or a history of prior perinatal illness are more likely to become ill in the current puerperium. Because many psychiatric disorders are more prevalent in women than in men, and most begin early in life, typically during or even before the reproductive years, clinicians routinely provide treatment to women for mental illnesses during the childbearing years. Efforts to determine the precise incidence of perinatal psychiatric illness are hindered by several factors: 1) the overlap of symptoms between certain mental illnesses and the normal sequelae of pregnancy, 2) the reliance on retrospective reports in many studies, and 3) the limited assessment of comorbid medical disorders that could contribute to psychiatric symptoms (e.g., anemia, thyroid dysfunction) (Pedersen et al. 1993).

PREVALENCE OF PSYCHIATRIC DISORDERS DURING PREGNANCY AND THE POSTPARTUM PERIOD

Despite the clinical lore that pregnancy is a time of emotional well-being, rates of depression during pregnancy are comparable to those of nonpuerperal depression (Buesching et al. 1988; Cutrona 1986; Kumar and Robson 1984; Manly et al. 1982; O'Hara et al. 1982; Watson et al. 1984). Two large investigations, collectively comprising 122,400 women, found a 14%–20% incidence of major depressive disorder during pregnancy (Marcus et al. 2003; Oberlander et al. 2006). In fact, more than 11% of women presenting for evaluation of postpartum depression report symptom onset during pregnancy (Stowe et al. 2005). Treatment discontinuation can be especially problematic. In a recent study by our group, pregnant women with a history of depression who discontinued antidepressant therapy proximate to conception were 2.6 times more likely to experience a relapse before delivery in comparison with those who continued antidepressant treatment (68% vs. 26%) (Cohen et al. 2006).

The perinatal course and management of bipolar disorder have come under increased scrutiny in the past decade. In an initial retrospective study, Grof et al. (2000) described a benign course for women with lithium-responsive bipolar disorder during pregnancy; however, most evidence indicates that

pregnant women with bipolar disorder are highly vulnerable to recurrence without continued pharmacotherapy. For example, three retrospective studies have reported 45%–52% bipolar disorder recurrence rates during pregnancy (Blehar et al. 1998; Freeman et al. 2000; Viguera et al. 2000). More recently, we have reported, in two separate prospective samples, relapse rates of 84%–100% among pregnant women with bipolar disorder who discontinue mood stabilizer therapy versus 30%–38% among those who continue mood stabilizer therapy (Newport et al. 2008b; Viguera et al. 2007).

Psychotic disorders have also been observed to worsen during pregnancy (Glaze et al. 1991; McNeil et al. 1984a, 1984b). Furthermore, women with schizophrenia have been reported to have high rates of unplanned and unwanted pregnancies (Miller 1997; Miller and Finnerty 1996) that may further escalate as SGAs with little impact on prolactin physiology (Dickson and Edwards 1997; Kaplan et al. 1996) become mainstays of therapy.

Although perinatal data regarding obsessive-compulsive disorder (OCD) are limited, it is noteworthy that 15%–39% of women with OCD report symptom onset during pregnancy (Neziroglu et al. 1992; K. E. Williams and Koran 1997). The course of OCD during pregnancy appears to be variable, with 73% of women reporting no symptom change, 14% reporting symptom exacerbation, and 14% reporting symptom improvement (Jenike et al. 1990; K. E. Williams and Koran 1997). The course of panic disorder during gestation is also highly variable, with 19% of patients experiencing more frequent panic attacks, 30% having reduced attacks, and 51% showing no change (Hertzberg and Wahlbeck 1999; Wisner et al. 1996a). Finally, a traumatic labor and delivery experience can precipitate posttraumatic stress disorder (Allen 1998; Fones 1996).

Postpartum psychiatric illness has been documented for millennia and has been substantiated by recent research. For example, a widely cited study by Kendler et al. (1993) reported a dramatic rise in psychiatric hospitalizations during the first postpartum month. In fact, up to 13% of all psychiatric admissions for women occur during the first postpartum year (Duffy 1983). Postpartum depression affects between 10% and 22% of adult women and up to 26% of adolescent mothers (Stowe and Nemeroff 1995; Troutman and Cutrona 1990). The postpartum is also a time of heightened risk for women with bipolar disorder (Kendell et al. 1987; Targum et al. 1979). Postpartum psychosis is thankfully a rare condition, occurring in only 1–2 of every 1,000 live births. Most postpartum psychoses appear to be psychotic episodes of a mood disorder (McGorry and Conell 1990).

EFFECT OF MATERNAL PSYCHIATRIC DISORDERS

Not only the likelihood but also the potential impact of maternal psychiatric illness on child well-being must be considered in the risk–benefit assessment. A salient feature of most mental disorders is impairment of function (American Psychiatric Association 2000), and intervention is clearly warranted if the impairment precludes a woman's participation in prenatal care or in some other manner jeopardizes the pregnancy or infant.

Obstetrical and developmental outcomes have been best studied in women experiencing depressive symptoms. For example, prenatal maternal depression may slow fetal growth (Hedegaard et al. 1996; Schell 1981), result in smaller infant head circumferences (Lou et al. 1994), increase the risk of preterm delivery and other obstetrical complications (Korebrits et al. 1998; Oberlander et al. 2006; Orr and Miller 1995; Perkin et al. 1993; Steer et al. 1992), and even precipitate long-standing behavioral changes in the offspring (Luoma et al. 2001, 2004; Meijer 1985; T. G. O'Connor et al. 2003; Stott 1973). Depressed gravidas are also more likely to abuse alcohol, engage in suicidal behavior, neglect prenatal care, and receive inadequate nutrition (Zuckerman et al. 1989), causing significant risk to the fetus (Perkin et al. 1993).

Maternal depression during pregnancy is also associated with neurobiological alterations in the offspring. For example, elevated serum concentrations of cortisol and catecholamines in depressed

third-trimester gravidas are correlated with urinary concentrations of these substrates in their infants 24 hours after delivery (Lundy et al. 1999).

Postnatal maternal depression also carries deleterious consequences for infant development. As early as 3 months, infants of depressed mothers exhibit less facial expression, less head orientation, less crying, and more fussiness than do infants of nondepressed mothers (Martinez et al. 1996). As they age, the children of depressed mothers display ineffective emotional regulation (Downey and Coyne 1990), slowed motor development evident as early as 6 months (Galler et al. 2000), and poorly integrated interactions even when the children of depressed mothers are interacting with nondepressed mothers (Jameson et al. 1997), and these children also show lower self-esteem beginning in preschool (Downey and Coyne 1990), more fear and anxiety (Lyons-Ruth et al. 2000), more aggression (Jameson et al. 1997), and more insecure and disorganized attachment behaviors (Martins and Gaffan 2000) than do children of nondepressed mothers. Children of depressed mothers are ultimately more likely to experience emotional instability, to have behavioral problems and suicidal behavior, and to require psychiatric treatment (Lyons-Ruth et al. 2000; Weissman et al. 1984).

The effect of other maternal psychiatric disorders on infant and neonatal development is less well investigated. Although formal studies are lacking, the poor judgment and reckless behavior that characterize manic episodes of bipolar disorder inarguably convey a host of risks to the developing child. The risks, if any, associated with maternal hypomania are less clear.

Perinatal exacerbation of schizophrenia and other psychotic illnesses also warrants concern. Women with schizophrenia have a higher prevalence of substance abuse during pregnancy (Miller and Finnerty 1996) and often exhibit bizarre ideas regarding contraception, pregnancy, and child rearing that complicate their perinatal course (McEvoy et al. 1983). Left untreated, schizophrenia during the peripartum can have devastating consequences for both mother and child. Cases exist of maternal self-mutilation (Coons et al. 1986; Yoldas et al. 1996), infanticide (Bucove 1968), and denial of pregnancy with consequent refusal of prenatal care (Slayton and Soloff 1981). In addition, children born to mothers with schizophrenia are more likely to suffer from obstetrical complications (Miller and Finnerty 1996), although a recent investigation did not confirm this finding (Bennedsen et al. 2001). Maternal schizophrenia is also associated with a higher rate of perinatal death (Rieder et al. 1975). Furthermore, mothers with schizophrenia often exhibit aberrant parenting styles that may contribute to the development of avoidant behaviors in their children (Riordan et al. 1999).

The impact of anxiety disorders on obstetrical outcomes remains obscure. A case series of eight women with OCD during pregnancy reported that two developed preeclampsia, three delivered prematurely, and five underwent cesarean section (Maina et al. 1999).

The clinical data regarding the obstetrical and developmental consequences of maternal mental illness are complemented by an extensive line of laboratory animal research bearing homology to depression and other stress-related psychiatric disorders (for a review, see Newport et al. 2002b). Consistent with the limited human database, animal research indicates that prenatal stress adversely affects offspring growth (Herrenkohl and Gala 1979; Schneider et al. 1999), learning ability (Jaiswal and Bhattacharya 1993; Smith et al. 1981; Weller et al. 1988), and postnatal development (Fride and Weinstock 1984).

Furthermore, preclinical research indicates that certain biobehavioral aberrations induced by prenatal stress may persist into adulthood. For example, prenatally stressed adult rats continue to demonstrate depression-like behaviors (Secoli and Teixeira 1998), anxiety-like behaviors in novel situations (Fride and Weinstock 1988; Poltyrev et al. 1996; Szuran et al. 1991; Vallee et al. 1997; Weinstock et al. 1988), and exaggerated "emotional" responses to stress (Fride et al. 1986; Pfister and Muir 1992; Wakshlak and Weinstock 1990). Prenatally stressed primates also exhibit diminished exploratory behavior (Clarke and Schneider 1993; Schneider 1992).

These behavioral alterations are accompanied by lasting neurobiological alterations. In particular, prenatally stressed animals demonstrate multiple alterations in hypothalamic-pituitary-adrenal (HPA) axis function, including the following: 1) increased basal concentrations of plasma corticosterone and adrenocorticotropic hormone (ACTH) (McCormick et al. 1995; Takahashi 1998; Takahashi and Kalin 1991), 2) heightened production of corticotropin-releasing factor (CRF) in the fetal hypothalamus (Fujioka et al. 1999), and 3) exaggerated corticosterone responses to subsequent mild stressors (Fride and Weinstock 1984; Henry et al. 1994; Peters 1982; Weinstock et al. 1992). The activity of catecholamine (Alonso et al. 1994, 1997; Fride et al. 1985; Henry et al. 1995; Peters 1982, 1984) and serotonin (Hayashi et al. 1998; Peters 1982, 1986, 1988, 1990) systems is also altered in prenatally stressed laboratory animals.

Laboratory paradigms that interfere with maternal care (e.g., maternal separation, variable foraging) precipitate similar adverse biobehavioral outcomes in the offspring. Offspring from these neonatal maternal stress protocols exhibit insecure attachment behaviors (Andrews and Rosenblum 1988, 1991, 1994; Rosenblum and Paully 1984), depression-like and anxiety-like behaviors (Levine 1967), and alterations in stress-respondent neurobiological systems (Coplan et al. 1996, 1998; Pauk et al. 1986; Pihoker et al. 1993; Walker et al. 1991). Although direct correlations between laboratory animal stress models and human psychiatric illness are difficult to sustain, these preclinical data underscore the potential long-term effects of maternal stress during the peripartum.

TREATMENT ISSUES DURING PREGNANCY AND LACTATION

An appraisal of the risks and benefits afforded by psychotropic treatment is the other major facet of the perinatal risk–benefit assessment. The theoretical risks of fetal and neonatal medication exposure may be classified as either acute or developmental adverse effects (Table 64–1). ***Acute effects*** are typically immediately evident and are not dependent on the developmental window of exposure. Examples of acute effects include drug toxicity, drug withdrawal, and drug–drug interactions. ***Developmental effects*** are, by definition, dependent on the developmental window of exposure and are often not evident until later. These effects include somatic teratogenesis (i.e., major and minor malformations) and so-called neurobehavioral teratogenesis (i.e., alterations in brain development that affect the child's subsequent behavior, cognitive abilities, and emotional regulation). The window of vulnerability to somatic teratogenesis is limited to the embryonic phase of development, but because CNS development continues long after delivery, the fetus and breast-feeding infant are vulnerable to the theoretical risk of neurobehavioral teratogenesis.

TABLE 64–1. Risks of perinatal medication exposure

	Acute	Developmental
Pregnancy	Neonatal toxicity	Somatic teratogenesis
	Neonatal withdrawal	Neurobehavioral teratogenesis
	Drug–drug interactions	
Lactation	Infant toxicity	Neurobehavioral teratogenesis
	Drug–drug interactions	

The risks of psychopharmacological exposure can be averted by using nonpharmacological treatment alternatives. Some of these therapies, including interpersonal psychotherapy (O'Hara et al. 2000; Spinelli 1997), cognitive-behavioral therapy (Appleby et al. 1997), sleep deprivation (B. L. Parry et al. 2000), and electroconvulsive therapy (Miller 1994), have been used in the peripartum and warrant consideration (Cohen et al. 1989; Miller 1991). These alternatives are not without shortcomings. They are often costly or unavailable in the rapidly evolving managed care environment, and they may take

longer to work than psychotropic medications. Any delay in therapeutic benefit thus extends the child's exposure to the risks associated with maternal mental illness. A recent meta-analysis that the treatment effect of perinatal psychotherapy is less than that of antidepressant pharmacotherapy, although synergistic effects can be achieved with concomitant administration of antidepressants and psychotherapy (Bledsoe and Grote 2006). Consequently, psychotropic medications remain the principal treatment offering for many, if not most, women with perinatal mental illness.

Deciding whether to use psychotropic medication during pregnancy and/or lactation carries complicated clinical, ethical, and potentially legal ramifications. A rapidly expanding data set regarding the reproductive safety of psychotropic medications has in part addressed many of these concerns, but these data span a broad literature in psychiatry, obstetrics, pediatrics, and basic science journals, limiting the ease of availability. In addition, the current literature regarding psychotropic medications during pregnancy and lactation reveals numerous methodological problems. The most glaring deficiency is the absence of an appropriate control group for comparison; therefore, psychotropic outcome studies are subject to the confounding effects of maternal psychiatric illness that may be misinterpreted as medication effects. Despite these limitations, ethical considerations preclude the possibility that well-controlled clinical trials will ever be conducted for psychotropic medication among pregnant or lactating women.

The use of psychotropic medications during pregnancy and lactation continues to generate considerable debate, and a final consensus is unlikely to be forthcoming. Adequately controlled studies to resolve these issues are equally unlikely. The pregnancy and lactation reproductive safety database for psychotropic medications is therefore composed of a diverse conglomeration of isolated case reports, case series by pharmaceutical companies and academic centers, birth registries, retrospective surveys, reports from teratology or poison control centers, more extensive clinical and preclinical pharmacokinetic investigations, an increasing array of review articles summarizing data from these primary sources, the American Academy of Pediatrics (2001) breast-feeding rating system, and the U.S. Food and Drug Administration (FDA) pregnancy rating system (Table 64–2). In the absence of controlled trials, it is not surprising that the FDA has not to date approved any psychotropic medication for use during pregnancy or lactation. The FDA pregnancy rating system is not without shortcomings. One potential confounder of this system is that medications that have been available longer are more likely to have accrued a greater number of adverse case reports than newer, less studied medications. Similarly, it is often difficult to track the process that actually contributes to the individual category ratings.

TABLE 64–2. U.S. Food and Drug Administration (FDA) use-in-pregnancy ratings

Category	Interpretation
A	**Controlled studies show no risk:** Adequate, well-controlled studies in pregnant women have failed to demonstrate risk to the fetus.
B	**No evidence of risk in humans:** Either animal findings show risk, but human findings do not; or, if no adequate human studies have been done, animal findings are negative.
C	**Risk cannot be ruled out:** Human studies are lacking, and animal studies are either positive for fetal risk or lacking as well. However, potential benefits may justify the potential risk.
D	**Positive evidence of risk:** Investigational or postmarketing data show risk to the fetus. Nevertheless, potential benefits may outweigh risks.
X	**Contraindicated in pregnancy:** Studies in animals or humans, or investigational or postmarketing reports, have shown fetal risk that clearly outweighs any possible benefit to the patient.

Source. Physicians' Desk Reference 2007.

Reviewing the reproductive safety database is only one aspect of assessing the relative utility of psychopharmacological treatment. A meticulous review of the patient's clinical history is also important. Obtaining comprehensive medical and obstetrical histories, particularly screening for a history of placental insufficiency, preeclampsia, and urinary or gastrointestinal disorders, is imperative. Early identification of probable perinatal comorbidities may guide the selection of psychotropic agents. For example, psychotropics with potent antihistaminic properties may complicate the course of overt or gestational diabetes during pregnancy, whereas other psychotropic agents (e.g., selective serotonin reuptake inhibitors [SSRIs]) may actually improve glycemic control. Potential drug interactions with medications used to manage medical comorbidities or with analgesic and anesthetic medications used at delivery should also be considered. Obtaining the patient's psychiatric history and family psychiatric history is also important, not only for clarifying the psychiatric diagnosis but also for providing documentation of responses to previous therapeutic trials of psychotropic medications. Regardless of the volume of reproductive safety data, a medication that has been poorly tolerated or ineffective for a particular patient is of little value.

PHARMACOKINETICS AND PHARMACODYNAMICS OF PREGNANCY AND LACTATION: IMPLICATIONS FOR DOSE MANAGEMENT

When the decision is made to use a psychotropic medication during pregnancy or lactation, it is important to administer the *minimum effective dose.* Clinicians commonly reduce the dose of psychotropic medication upon learning that a patient is pregnant, in a well-meaning effort to reduce fetal medication exposure. However, indiscriminate dosage reduction also increases the patient's vulnerability to relapse. Inadequate dosing therefore unduly exposes the child to the risks of both medication and maternal illness, yet administering doses higher than those necessary to achieve and sustain remission is equally inadvisable. Inordinately high doses expose the child to unnecessarily high medication concentrations. The therapeutic goals of psychopharmacological treatment during pregnancy and lactation are 1) to eliminate the child's exposure to maternal illness by achieving clinical remission while 2) minimizing the child's exposure to psychotropic medication. To accomplish these concomitant goals, dose management during pregnancy and lactation must be informed by an understanding of the factors governing the placental passage and breast milk excretion of psychotropic medications as well as of the impact of the physiological changes of pregnancy on the pharmacological effects of these medicines.

It is well recognized that dosage adjustments are often required to maintain the therapeutic efficacy of medications during pregnancy. For example, it may be necessary to increase the dose of tricyclic antidepressants (TCAs) to approximately 1.6 times the preconception dose to maintain therapeutic concentrations in late pregnancy (Altshuler et al. 1996; Wisner et al. 1993). Similar increases may be required with SSRIs during the early third trimester to sustain euthymia (Hostetter et al. 2000). However, the pattern of dose adjustment during gestation is not uniform for all medications. For example, among anticonvulsant/mood-stabilizing medications, serum concentrations of lamotrigine (I. Ohman et al. 2000; Pennell et al. 2000; Tran et al. 2002) and valproic acid (Otani 1985; Philbert et al. 1985) decline steadily across gestation, whereas carbamazepine concentrations (Bardy et al. 1982b; Battino et al. 1982; Bologa et al. 1991; Dam et al. 1979; Lander et al. 1980; Omtzigt et al. 1993; Otani 1985; Tomson et al. 1994; Yerby et al. 1985) exhibit smaller changes that are primarily evident only in late pregnancy. Increasing evidence indicates that these alterations in drug concentrations and dosing requirements are a consequence of the impact of the physiological changes of pregnancy on the pharmacokinetics (Boobis and Lewis 1983; Frederiksen 2001; Little 1999; Wyska and Jusko 2001), and possibly the pharmacodynamics (Wyska and Jusko 2001), of psychotropic medications.

Each of the four generally recognized phases of the pharmacokinetic sequence—absorption, distribution, metabolism, and excretion—is affected by pregnancy. Several factors serve to increase the *absorption* of orally administered medications during gestation. Decreases in the rate of gastric

emptying (Hunt and Murray 1958) and intestinal motility (E. Parry et al. 1970) lengthen the transit time of oral medications and thus increase the time for absorption across the intestinal mucosa. In addition, heightened blood flow to the digestive tissues (Mattison 1986) increases the rate of absorption.

Drug *distribution* is also altered during gestation. Both plasma volume (Lund and Donovan 1967; Mattison et al. 1991) and extracellular fluid volume (Mattison et al. 1991; Petersen 1957; Plentl and Gray 1959) increase dramatically. In addition, increases in body fat during pregnancy (Mattison et al. 1991) further expand the volume of distribution for psychotropic medications, which are almost uniformly highly lipophilic compounds. The dilutional effect of the increased volume of distribution is offset somewhat by decreased concentrations of circulating plasma proteins such as albumin (Frederiksen et al. 1986; Mendenhall 1970; Perucca and Crema 1982), serving to increase the distribution of many compounds into the bioavailable free fraction. However, plasma concentrations of some plasma proteins are relatively unchanged (e.g., α_1-acid glycoprotein [Wood and Wood 1981]) or even increased (e.g., sex hormone–binding globulin [Perucca and Crema 1982]) during pregnancy. Alterations in the unbound fraction arising from gestational changes in plasma protein concentrations impact the availability of medications not only for bioactivity but also for metabolic degradation.

Rates of drug *metabolism* during pregnancy are also affected by other mechanisms. First, tissue delivery of medication is increased during pregnancy by the increase (up to 50%) in cardiac output (Lees et al. 1967), but a smaller percentage of this heightened cardiac output is delivered to the liver as more blood is diverted to the uterus and other organs (Robson et al. 1990). Second, pregnancy is associated with numerous changes in the activity of various hepatic and extrahepatic enzymes. The activity of the hepatic cytochrome P450 (CYP) 3A4 (Bologa et al. 1991; Homma et al. 2000) isoenzyme is increased during gestation but that of CYP1A2 (Bologa et al. 1991; Tsutsumi et al. 2001) is decreased. CYP2D6 activity is increased during pregnancy in all women except those who are pharmacogenetically poor CYP2D6 metabolizers (Wadelius et al. 1997). Many CYP isoenzymes are also present in placental tissue, although the activity of the placental enzymes appears to be considerably lower than that of their hepatic counterparts (Hakkola et al. 1996).

Finally, drug *elimination* during pregnancy is affected by increases in renal blood flow (Metcalfe et al. 1955) and glomerular filtration rate (Davison and Hytten 1974; Dunlop 1981). In summary, the pharmacokinetic alterations of pregnancy are governed by a complex set of interdependent variables that remain obscure but may ultimately provide a basis from which to construct rational models for dosing guidelines during gestation.

Dose management during the peripartum may also be affected by alterations in the pharmacodynamics of psychotropic agents. Even less is known regarding the impact of the physiology of pregnancy on pharmacodynamics, but indications that postpartum depression is associated with alterations in the binding affinity of platelet serotonin transporters for radiolabeled imipramine and paroxetine (Hannah et al. 1992; Newport et al. 2004) lend credence to the existence of puerperal pharmacodynamic alterations. Pharmacodynamic indirect response models and signal transduction models (Wyska and Jusko 2001) offer plausible mechanisms whereby drug activity is altered during gestation. Additional candidate models of pharmacodynamic alterations during pregnancy remain to be explored.

The extent of fetal psychotropic exposure is the other principal consideration when administering medication during gestation. Fetal psychotropic exposure is largely dictated by placental passage of the medication, and all psychotropic medications are presumed to cross the placenta. Rates of placental transfer can be grouped into three categories (Pacifici and Nottoli 1995):

- *Type I: complete transfer*—Medication concentrations rapidly equilibrate between the maternal and fetal compartments.

- *Type II: excessive transfer*—Fetal concentrations are greater than maternal concentrations.
- *Type III: incomplete transfer*—Fetal concentrations are less than maternal concentrations.

Although there is no immediate evidence of placental filtering of psychotropic medications, there are significant differences in the rates of placental passage among antidepressants (Hendrick et al. 2003b) and antipsychotics (Newport et al. 2007). The primary mechanism of placental transport is simple diffusion, and its rate largely depends on the physicochemical properties of the particular medication. The major determinants of a medication's rate of diffusion across the placenta are molecular weight, lipid solubility, degree of ionization, and protein binding (Audus 1999; W. M. Moore et al. 1966; Pacifici and Nottoli 1995); however, the relative importance and critical thresholds for the respective physicochemical properties are yet to be delineated. At least one transplacental active transport mechanism has been identified. Placental glycoprotein (PGP) actively transports substrates from the fetal circulation back to the maternal circulation. Consequently, medications with greater affinity for PGP should be associated with relatively lower fetal-to-maternal medication ratios, as we recently demonstrated in an investigation of antipsychotic placental passage (Newport et al. 2007). Further clarification of the pharmacological attributes governing placental passage may ultimately contribute to the identification and development of efficacious psychotropic agents with minimal rates of placental transfer (Wang et al. 2007).

Fetal plasma concentrations are not, however, the ultimate measure of functional psychotropic exposure and may even underestimate the more critical measure, fetal brain concentration. Certain physiological attributes of the human fetus, including high cardiac output, increased blood–brain barrier permeability, low plasma protein concentrations and plasma protein binding affinity, and low hepatic enzyme activity (Bertossi et al. 1999; Morgan 1997; Oesterheld 1998), may result in higher fetal CNS concentrations of psychotropic medications than might be anticipated from circulating levels. Preclinical investigations from our group have demonstrated that transplacental passage results in high levels in fetal brain tissues and significant binding at neurotransmitter uptake sites (A. D. Fisher et al. 2001; Graybeal et al. 2002; Owens et al. 1997).

Similar considerations apply when endeavoring to minimize the psychotropic exposure of infants whose mothers are receiving psychiatric medication during lactation. After delivery, the neonate continues to exhibit unique physiological characteristics, including relatively low activity of hepatic enzymes. Hepatic maturation in the infant appears to occur at a highly variable rate (Warner 1986) and is more delayed in premature infants. Both glucuronidation and oxidation systems are initially immature at birth (as low as 20% of adult levels). The latter system typically matures by age 3 months (Atkinson et al. 1988). In addition, rates of glomerular filtration and tubular secretion are relatively low in neonates—30%–40% and 20%–30% lower than adult levels, respectively (Welch and Findlay 1981). Hence, the potential that psychotropic exposure may be higher than anticipated remains a consideration for breast-fed infants.

Because medications predominantly enter breast milk by passive diffusion of the nonionized, unbound fraction (J. T. Wilson et al. 1980), the pH gradient between maternal serum and breast milk plays a significant role in the amount of medication that is excreted into breast milk. Medications may in certain instances become ion-trapped in milk. The lower pH of human milk may alter the molecular structure of a medication, preventing its reperfusion into the maternal circulation (Agatonovic-Kustrin et al. 2002). In addition, active secretory mechanisms also exist that can further concentrate drugs in breast milk (Kari et al. 1997; Oo et al. 1995; Toddywalla et al. 1997). A model to predict rates of breast milk excretion from descriptive characteristics of the molecular structure of candidate medications has recently been proposed (Agatonovic-Kustrin et al. 2002).

One purpose of such models is to provide a means to forecast infant exposure without performing invasive procedures on the child. Most familiar approaches utilize maternal serum concentrations and/or breast milk concentrations to calculate a milk-to-plasma ratio that is in turn used to calculate

the infant's "daily dose" acquired through breast-feeding. Unfortunately, many existing studies calculate the milk-to-plasma ratio from a single random breast milk sample. This simplistic approach ignores the pharmacokinetics of medication excretion in breast milk and may thus provide an inaccurate prediction of infant exposure.

Accurately forecasting the level of infant exposure via lactation necessitates consideration of two well-described excretion gradients: distribution gradient and time gradient (Stowe et al. 1997, 2000). First, a distribution gradient of medication concentration in human milk exists during the course of a single feeding. As a rule, psychotropic medications are highly lipophilic and therefore present in higher concentrations in the fatty hindmilk. Consequently, a milk–plasma ratio calculated from an isolated random milk sample can vary widely between foremilk and hindmilk collections. In addition, a dose-to-dose time gradient for psychotropic excretion into breast milk also exists. The time course of psychotropic excretion into breast milk is largely consistent with the gastrointestinal absorptive phase of these medications and thus can largely be predicted by their known pharmacokinetics. For example, peak breast milk concentrations of sertraline occur at about 8 hours after the last dose, whereas the nadir occurs just prior to the next dose. Accurate prediction of daily infant dose via breast-feeding requires a model that acknowledges these excretion gradients. Utilizing this type of model, our group completed a detailed study of both the pharmacokinetics of excretion and infant serum measures for sertraline demonstrating that the maximum calculated infant dose is typically less than 1/500 of the maternal dose (Stowe et al. 1997).

ANTIDEPRESSANTS

Antidepressant medications are used to treat a variety of neuropsychiatric illnesses. Commonly prescribed antidepressants are listed in Table 64–3. According to recent reports, 6.6% of pregnant women receive a prescription for an antidepressant at some point during pregnancy (Andrade et al. 2008).

TABLE 64–3. Antidepressant medications

Generic name	Trade name	Daily dose (mg/day)[a]	Risk category[b]	American Academy of Pediatrics rating[c]
Selective serotonin uptake inhibitors				
Citalopram	Celexa	20–60	C	Unknown, but of concern
Escitalopram	Lexapro	5–20	C	N/A
Fluoxetine	Prozac	20–60	C	Unknown, but of concern
Fluvoxamine	Luvox	50–300	C	Unknown, but of concern
Paroxetine	Paxil	20–50	D	Unknown, but of concern
Sertraline	Zoloft	50–200	C	Unknown, but of concern
Tricyclic antidepressants				
Amitriptyline	Elavil, Endep	150–300	D	Unknown, but of concern
Amoxapine	Asendin	150–400	C_m	Unknown, but of concern
Clomipramine	Anafranil	150–250	C_m	Unknown, but of concern[d]
Desipramine	Norpramin	150–300	C	Unknown, but of concern
Doxepin	Sinequan, Adapin	150–300	C	Unknown, but of concern
Imipramine	Tofranil	150–300	D	Unknown, but of concern

Generic name	Trade name	Daily dose (mg/day)[a]	Risk category[b]	American Academy of Pediatrics rating[c]
Maprotiline	Ludiomil	140–225	B_m	N/A
Nortriptyline	Pamelor, Aventyl	75–150	D	N/A
Protriptyline	Vivactil	15–60	C	N/A
Monoamine oxidase inhibitors				
Isocarboxazid	Marplan	30–60	C	N/A
Phenelzine	Nardil	45–90	C	N/A
Tranylcypromine	Parnate	30–60	C	N/A
Other antidepressants				
Bupropion	Wellbutrin	150–450	C	Unknown, but of concern
Duloxetine	Cymbalta	30–90	C	N/A
Mirtazapine	Remeron	15–45	C	N/A
Nefazodone	Serzone	300–600	C	N/A
Trazodone	Desyrel	200–300	C	Unknown, but of concern
Venlafaxine[e]	Effexor	150–375	C	N/A

Note. N/A = not available.

[a]Dosing strategies adapted from Schatzberg and Cole 1991; Kaplan and Sadock 1993; and, for newer medications, the manufacturers' package inserts.

[b]Risk category adapted from Briggs et al. 2005 and/or *Physicians' Desk Reference* 2007; "m" subscript indicates data taken from the manufacturer's package insert.

[c]American Academy of Pediatrics 2001.

[d]Original committee report 1994 listed as "compatible," and a correction was later published.

[e]Not listed in Briggs et al. 1994. Risk category taken from *Physicians' Desk Reference* (1992, 1993, 1994, and 1996 editions).

Selective Serotonin Reuptake Inhibitors

SSRI antidepressants, among the best-studied medications in pregnancy and the single best-studied class of medications in lactation, have emerged as first-line agents for treating depression during pregnancy and lactation.

Prospective reports of first-trimester SSRI use currently consist of 4,679 fluoxetine exposures resulting in 126 (2.7%) children with major malformations (Briggs et al. 2005; Chambers et al. 1996; GlaxoSmithKline 2005; Goldstein et al. 1997; Hallberg and Sjöblom 2005; McElhatton et al. 1996; Pastuszak et al. 1993; Wilton et al. 1998), 3,393 sertraline exposures with 66 (1.9%) major malformations (GlaxoSmithKline 2005; Hallberg and Sjöblom 2005; Kulin et al. 1998; Wilton et al. 1998), 2,688 citalopram exposures with 73 (2.7%) major malformations (Ericson et al. 1999; GlaxoSmithKline 2005; Hallberg and Sjöblom 2005; Heikkinen et al. 2002; Sivojelezova et al. 2005), 2,687 paroxetine exposures with 94 (3.5%) major malformations (GlaxoSmithKline 2005; Hallberg and Sjöblom 2005; Kulin et al. 1998; McElhatton et al. 1996; Wilton et al. 1998), 235 escitalopram exposures with 8 (3.4%) major malformations (GlaxoSmithKline 2005), 147 fluvoxamine exposures with 1 (0.7%) major malformation (GlaxoSmithKline 2005; Kulin et al. 1998; McElhatton et al. 1996; Wilton et al. 1998), and 395 exposures to unspecified SSRIs with 6 (1.5%) major malformations

(Einarson et al. 2001; Ericson et al. 1999; Hendrick et al. 2003a; Simon et al. 2002; Sivojelezova et al. 2005). The 2.6% (*n* = 374) overall SSRI malformation rate among these 14,224 pregnancies is consistent with rates reported in the general population (New York State Department of Health 2005; Rimm et al. 2004; Swedish Centre for Epidemiology 2004).

Despite these reassuring and voluminous data, some concerns have been raised. For example, a preliminary analysis of a managed care database demonstrated a statistically higher odds ratio for major malformations, particularly cardiovascular malformations, after first-trimester paroxetine exposure in comparison to exposure to other antidepressants (GlaxoSmithKline 2005), leading the FDA to reclassify paroxetine's pregnancy category (U.S. Food and Drug Administration 2005). Although the FDA deemed the data sufficiently compelling to alter the pregnancy classification, definitive conclusions are precluded by numerous limitations in this data set (e.g., there is no nonexposed control group, the paroxetine malformation rates reported in this study approximate population norms, and the significant finding in one arm of the study is eliminated when those with exposure to other known teratogens are excluded).

Three recent large-scale case–control studies of first-trimester SSRI exposure have likewise produced generally reassuring results, although some concerns have emerged. One of these studies comparing 9,622 cases (infants with malformations) and 4,092 controls (infants without malformations) found no evidence to suggest that SSRI exposure was associated with higher rates of cardiovascular defects but did report small increases in the risk for three uncommon malformations—anencephaly (odds ratio [OR] = 2.4), craniosynostosis (OR = 2.5), and omphalocele (OR = 2.8) (Alwan et al. 2007). Conversely, a study comparing 9,489 cases and 5,860 controls found no evidence of increased risk for heart defects of these other three malformations with first-trimester SSRI exposure (Louik et al. 2007). Analysis of individual antidepressants in the second study did demonstrate an increased risk for omphalocele (OR = 5.7) and septal defects (OR = 2.0) with sertraline exposure, and for right ventricular outflow tract obstruction defects (OR = 3.3) with paroxetine exposure. Finally, a nested case–control study of 1,403 infants, including 101 with major malformations, found no evidence that SSRI or paroxetine use was associated with an increased risk for cardiovascular or other major malformations, unless women were administered ≥25 mg of paroxetine per day, in which case their infants were at higher risk for cardiovascular malformations (OR = 3.1) and overall malformations (OR = 2.2).

The first investigation of the neurobehavioral impact of prenatal SSRI exposure is a landmark study by Nulman et al. (1997a) of children exposed in utero to antidepressant medications (55 fluoxetine-exposed children, 80 TCA-exposed children, 84 children with no antidepressant exposure). Children between 16 months and 7 years of age were evaluated with an extensive battery of neurodevelopmental tools measuring global intelligence quotient (IQ), language development, temperament, mood, activity level, and behavior. No significant differences on any of the neurodevelopmental measures were detected among the three groups of children in the study. Furthermore, global IQ and language development were nearly identical among all the groups. In conclusion, there was no apparent neurobehavioral impact of prenatal exposure to fluoxetine or TCAs on children of preschool or early elementary school age.

To date, few studies have systematically assessed child development after prenatal antidepressant exposure. The first two reports, from the same group, assessed children between 15 and 86 months of age, collectively comparing 126 children exposed prenatally to a TCA and 90 children exposed to fluoxetine with 120 children of women with no history of depression. Using age-adjusted rating instruments, they found no differences with respect to global cognition, psychomotor development, or language development (Nulman et al. 1997a, 2002). The third study, assessing children between 6 and 40 months of age, compared 13 children whose mothers were depressed but did not take antidepressant medication during pregnancy with 31 children who were prenatally exposed to an

SSRI (Casper et al. 2003). Like the Nulman et al. studies, this group also found no differences in global cognition; however, lower psychomotor scores were reported for the SSRI-exposed children.

Unfortunately, limitations of these three studies render their implications speculative at best. First, children were not age-matched in any of these studies. Although the authors reported age-adjusted index scores, the predictive validity of these indices across child developmental stages has not been established (Black and Matula 2000). Consequently, groupwise differences in the ages of the children might confound the results. Second, the Casper et al. (2003) study is further confounded by the fact that 29% of the participants were enrolled after delivery. This inclusion of a retrospective (postnatally enrolled) sampling could result in an overrepresentation of children with developmental abnormalities.

Another recent investigation (Oberlander et al. 2004) evaluated children at fixed time points (2 months and 8 months of age), thereby eliminating the age adjustment confound. This study reported no difference between 46 SSRI-exposed infants and 23 children of healthy volunteers with respect to either cognitive or motor development. Finally, a recent assessment of externalizing and attentional behaviors in 4-year-old children found no evidence that prenatal SSRI exposure affected these outcomes (Oberlander et al. 2007).

Although evidence regarding the developmental effects of SSRI exposure has been reassuring, data on the impact of prenatal antidepressant exposure on vulnerability to miscarriage, preterm delivery, and/or low birth weight are decidedly mixed. Some investigators have reported an association with such outcomes (Chambers et al. 1996; Chun-Fai-Chan et al. 2005; Oberlander et al. 2006; Pastuszak et al. 1993; Simon et al. 2002), whereas others have not (Einarson et al. 2001, 2003; Kulin et al. 1998; Sivojelezova et al. 2005). This is further complicated by yet other studies reporting an association of prenatal maternal stress and/or depression with prematurity and low birth weight (Orr et al. 2002; Steer et al. 1992). As such, no definitive conclusions can be drawn as to whether antidepressant use during gestation conveys an adverse impact on fetal growth or the timing of parturition.

Finally, a transient self-limited syndrome of neonatal symptoms, most commonly respiratory difficulty and tremulousness/jitteriness, associated with fetal exposure to serotonergic antidepressants proximate to delivery has drawn increasing attention (Moses-Kolko et al. 2005). Most controlled prospective studies suggest that there may be an association between SSRI exposure and poor neonatal adaptation (Chambers et al. 1996; Costei et al. 2002; Källén 2004; Laine et al. 2003; Oberlander et al. 2004, 2006; Sivojelezova et al. 2005; Zeskind and Stephens 2004), although one recent study found no such association (Maschi et al. 2008) and closer scrutiny of these reports reveals a cadre of methodological shortcomings. Little effort has been made to mask those evaluating the neonates as to fetal antidepressant exposure, only one study (Oberlander et al. 2006) has endeavored to control for the impact of maternal mental illness, and key confounding exposures such as gestational age at delivery, maternal smoking, and/or maternal use of other medications have been either ignored altogether or controlled in the crudest fashion (as dichotomous variables derived from unconfirmed maternal self-report). The most recent and arguably best designed of these studies (Oberlander et al. 2006) reported a significant association of SSRI exposure with neonatal respiratory difficulty and small-for-gestational-age birth weight; however, the authors failed to highlight the significant associations in their data of maternal depression during pregnancy with cesarean section delivery, preterm delivery, longer duration of neonatal hospital stay, and neonatal feeding problems.

A putative mechanism for SSRI-associated neonatal respiratory difficulty has been suggested by a recent retrospective case–control study (Chambers et al. 2006) reporting an overrepresentation of SSRI exposure after gestational week 20 among neonates with persistent pulmonary hypertension (PPHN) (OR = 6.1). However, the fact that only 3.7% of the neonates with PPHN were exposed to an SSRI in late pregnancy, coupled with the recognition that PPHN is itself a relatively rare condition affecting approximately 0.19% of newborns (Greenough and Khetriwal 2005), raises questions as to

whether this statistically significant finding is as clinically meaningful as the authors contend.

Another recent case–control study, comparing the exposures of neonates who "required observation" with those of "healthy" neonates (Misri et al. 2004), further highlights the importance of controlling for confounding factors. In this study, in which all neonates (*n* = 46) were exposed to antidepressants and born to mothers who fulfilled diagnostic criteria for major depressive disorder, the mothers of infants who required observation had significantly higher scores on the Hamilton Rating Scale for Depression (21.7 vs. 16.2) and the Hamilton Anxiety Scale (21.1 vs. 13.6), were significantly more likely to have a comorbid anxiety disorder (92.8% vs. 53.1%), and were on average exposed to higher doses of clonazepam (0.43 mg/day vs. 0.14 mg/day).

Pharmacokinetic data regarding the placental passage of SSRI antidepressants remain limited. A recent study by Hendrick et al. (2003b) demonstrated that mean fetal–maternal ratios of the plasma concentrations of several SSRIs (i.e., fluoxetine, fluvoxamine, paroxetine, and sertraline) and their active metabolites are uniformly less than 1, although considerable differences exist between medications. Data on in vivo placental passage of citalopram are not yet available. Investigations that will enable the elaboration of comprehensive pharmacodynamic models to guide SSRI dose management throughout gestation are currently under way.

Published reports pertaining to SSRIs and lactation now exceed the published literature for any other class of medications, encompassing numerous exposures to sertraline (Altshuler et al. 1995; Birnbaum et al. 1999; Dodd et al. 2000; C. Epperson et al. 1997; N. Epperson et al. 2001; Hendrick et al. 2001; Kristensen et al. 1998; Mammen et al. 1997; Stowe et al. 1997, 2000; Wisner et al. 1998), fluoxetine (Birnbaum et al. 1999; Burch and Wells 1992; Nonacs and Cohen 2002; Kristensen et al. 1999; Lester et al. 1993; Taddio et al. 1996; Yoshida et al. 1998a), paroxetine (Birnbaum et al. 1999; Hendrick et al. 2001; R. Ohman et al. 1999; Spigset et al. 1996; Stowe et al. 2000), escitalopram (Rampono et al. 2006), fluvoxamine (Hendrick et al. 2001; Piontek et al. 2001; Wright et al. 1991), and citalopram (Jensen et al. 1997; Schmidt et al. 2000; Spigset et al. 1997). Although infant follow-up data are limited, only a few isolated cases of adverse effects have been reported. Long-term neurobehavioral studies of infants exposed to SSRI antidepressants during lactation have not been conducted, although a study of 12 infants exposed to sertraline during nursing detected no adverse effects on growth or achievement of developmental milestones (Llewellyn et al. 1997).

Pharmacokinetic studies of SSRIs in lactation constitute a confusing array of investigations employing varying assay sensitivities and inconsistent collection methods that complicate efforts to compare rates of breast milk excretion between compounds. The pharmacokinetic profiles of breast milk excretion, including delineation of distribution gradients and time gradients, are best defined for sertraline (Stowe et al. 1997; Hendrick et al. 2003b), paroxetine (Stowe et al. 2000), and fluoxetine (Suri et al. 2002). Collectively, findings from these studies indicate that quantitative infant SSRI exposure during lactation is considerably lower than transplacental exposure to these same medications during gestation.

Tricyclic Antidepressants

TCAs have been available in the United States since 1963 and were widely used during pregnancy and lactation before the proliferation of reproductive safety data regarding the SSRIs. No clear association has been demonstrated between TCA exposure and congenital malformations. Early studies suggested that TCA exposure might be associated with limb anomalies (Barson 1972; Elia et al. 1987; McBride 1972), but a meta-analysis by Altshuler et al. (1996) of 14 studies representing more than 300,000 live births identified a congenital malformation incidence of only 3.14% (*n* = 13) among 414 infants exposed to a TCA during the first trimester. A review of data from the European Network of Teratology Information Services revealed similar rates of malformation after TCA exposure (McElhatton et al. 1996). These rates are well within the normal baseline incidence of 2%–4%. Furthermore, the

landmark study by Nulman et al. (1997a) involving 80 children exposed to a TCA during gestation found no evidence that prenatal exposure to these medications is associated with adverse neurobehavioral effects.

Few data exist regarding the acute effects of TCA exposure on fetal and neonatal well-being. There are case reports of fetal tachycardia (Prentice and Brown 1989) and numerous neonatal symptoms, including tachypnea, tachycardia, cyanosis, irritability, hypertonia, clonus, and spasm (Eggermont 1973; Miller 1991; Webster 1973). A small (*n* = 18) prospective study identified no evidence of increased complications during labor and delivery but did report transient withdrawal symptoms among TCA-exposed neonates (Misri and Sivertz 1991).

In a pharmacokinetic investigation addressing nortriptyline dose management during gestation, Wisner et al. (1993) reported that dose increases approximately 1.6 times higher than the preconception dose might be required in late pregnancy to maintain therapeutic serum concentrations and thereby sustain clinical benefit.

TCAs also have been widely used during lactation. The only adverse event reported to date is respiratory depression in a nursing infant exposed to doxepin, leading the authors to conclude that doxepin should be avoided but that most TCAs are safe for use during breast-feeding (Matheson et al. 1985). This clinical finding is paralleled by the pharmacokinetic data regarding TCAs in which all TCAs are evident in breast milk, but infant plasma concentrations are considerably higher for doxepin than for other TCAs (for a review, see Wisner et al. 1996b). The time gradient for excretion also has been reported, with peak breast milk concentrations occurring 4–6 hours after an oral dose of both amitriptyline (Pittard and O'Neal 1986) and desipramine (Stancer and Reed 1986).

Monoamine Oxidase Inhibitors

Although the monoamine oxidase inhibitors (MAOIs) were introduced more than 40 years ago, clinical data regarding their use during pregnancy and lactation are limited. The currently available MAOIs (i.e., isocarboxazid, phenelzine, and tranylcypromine) are all FDA Category C medications; however, a small prospective study (Heinonen et al. 1977) suggested that prenatal tranylcypromine exposure is associated with increased risk for fetal malformations. Laboratory animal studies also have reported teratogenic potential from embryonic exposure to MAOIs (Poulson and Robson 1964). The utility of MAOIs during pregnancy and lactation is severely limited by the potential for hypertensive crisis, which necessitates dietary constraints and avoidance of numerous medications that are commonly used during pregnancy (e.g., pseudoephedrine) or labor and delivery (e.g., meperidine). These restrictions can be avoided, at least in part, with the so-called reversible MAOIs (i.e., brofaromine and moclobemide). The reversible MAOIs are not currently available in the United States. The single published case report regarding moclobemide exposure during gestation reported no perinatal complications and indicated that the child demonstrated normal somatic and motoric development up to 14 months of age (Rybakowski 2001).

Other Antidepressants

Reproductive safety data are considerably more limited for most of the agents comprising the heterogeneous assortment of other antidepressants, including bupropion, duloxetine, mirtazapine, nefazodone, trazodone, and venlafaxine.

Prospective reports of first-trimester use of these agents consist of 2,550 bupropion exposures producing 56 (2.2%) children with major malformations (Boshier et al. 2003; Briggs et al. 2005; Chun-Fai-Chan et al. 2005; Cole et al. 2007; GlaxoSmithKline 2005), 771 venlafaxine exposures with 14 (1.4%) major malformations (Einarson et al. 2001; GlaxoSmithKline 2005), 404 trazodone exposures with 10 (2.5%) major malformations (Briggs et al. 2005; GlaxoSmithKline 2005; McElhatton et al. 1996), 140 nefazodone exposures with 2 (1.4%) major malformations (GlaxoSmithKline 2005),

125 mirtazapine exposures with 2 (1.6%) major malformations (Djulus et al. 2006; GlaxoSmithKline 2005), and an additional combined report of 121 nefazodone or trazodone exposures with 2 (1.7%) major malformations (Einarson et al. 2003). There are no published data on first-trimester duloxetine exposure.

Pharmacokinetic data during pregnancy are available only for venlafaxine. The pharmacokinetic study by Hendrick et al. 2003b reported that fetal–maternal plasma ratios for both venlafaxine and its active metabolite, *O*-desmethylvenlafaxine, are greater than 1. This higher rate of placental passage may be a consequence of certain physicochemical properties of venlafaxine, including its relatively low molecular weight and low binding to plasma proteins.

Data regarding the use of atypical antidepressants during lactation are likewise extremely limited. The existing literature includes reports of one infant exposed to bupropion (Briggs et al. 1993) and three infants exposed to venlafaxine (Ilett et al. 1998). No adverse effects were reported for any of these four children. Bupropion was undetectable in the plasma of the infant whose mother was taking that antidepressant (Briggs et al. 1993), but the plasma concentration of *O*-desmethylvenlafaxine was higher in one of the venlafaxine-exposed infants than in her mother (Ilett et al. 1998).

MOOD-STABILIZING MEDICATIONS

The perinatal management of bipolar disorder has received considerable attention and continues to be one of the most difficult challenges of modern psychiatric practice. The current mainstays of treatment for bipolar disorder are lithium, valproate, carbamazepine, and lamotrigine (Table 64–4).

TABLE 64–4. Mood-stabilizing and antiepileptic medications

Generic name	Trade name	Daily dosage (mg/day)[a]	Risk category[b]	American Academy of Pediatrics rating[c]
Carbamazepine	Tegretol	400–1,600	C_m	Compatible
Clonazepam	Klonopin	0.5–10	C	N/A
Gabapentin	Neurontin	900–1,800	C	N/A
Lamotrigine	Lamictal	300–500	C	Unknown, but of concern
Levetiracetam	Keppra	500–3,000	C	N/A
Lithium carbonate	Eskalith, Lithobid, Lithonate	900–2,100	D	Contraindicated
Oxcarbazepine	Trileptal	600–1,200	C	Unknown, but of concern
Tiagabine	Gabatril	160–320	C	N/A
Topiramate	Topamax	200–800	C	Unknown, but of concern
Valproic acid	Depakote (divalproex sodium)	750–1,500	D	Compatible

Note. N/A = not available.

[a]Dosing strategies adapted from Schatzberg and Cole 1991; Kaplan and Sadock 1993; and for newer medications, the manufacturers' package inserts.

[b]Risk category adapted from Briggs et al. 2005 and/or *Physicians' Desk Reference* 2007; "m" subscript indicates data taken from the manufacturer's package insert.

Lithium

Used routinely since the 1950s, lithium remains the cornerstone of the available pharmacotherapies

for bipolar disorder. Early reports of congenital malformations following in utero lithium exposure led to the establishment of the Danish Registry of Lithium Babies in 1969. Additional registries were later established in Canada and the United States, culminating in the International Register of Lithium Babies.

Early retrospective data suggested that lithium exposure was associated with a 400-fold increase in the vulnerability to congenital heart disease, with particular susceptibility to a malformation of the tricuspid valve known as Ebstein's anomaly (Nora et al. 1974; Weinstein and Goldfield 1975), but a subsequent meta-analysis of the available data calculated the risk ratio for cardiac malformations to be 1.2–7.7 and the risk ratio for overall congenital malformations to be 1.5–3.0 (Cohen et al. 1994). Altshuler et al. (1996) estimated that the risk for Ebstein's anomaly after prenatal lithium exposure rises from 1 in 20,000 to 1 in 1,000. A series of more recent yet small studies also failed to confirm the early estimates regarding the teratogenic potential of lithium (Friedman and Polifka 2000; Jacobsen et al. 1992; Källén and Tandberg 1983), although these studies had limited statistical power. Laboratory animal studies had indicated that neurobehavioral alterations also might be a concern for prenatal lithium exposure, but a 5-year follow-up of 60 school-age children exposed to lithium during gestation found no overt evidence of adverse neurobehavioral sequelae (Schou 1976).

Preconception counseling with a psychiatrist, obstetrician, and perhaps a genetic counselor should be the standard of care for women with bipolar disorder. Cohen et al. (1994) suggested the following treatment guidelines for women who are maintained on lithium and plan to conceive: 1) lithium should be gradually (>2 weeks) tapered prior to conception in women who experience mild and infrequent episodes of illness; 2) lithium should be tapered prior to conception but reinstituted after organogenesis in women who have more severe episodes but are only at moderate risk for relapse in the short term; 3) lithium should be continued throughout gestation for women who have especially severe and frequent episodes of illness in conjunction with counseling regarding reproductive risks. Prenatal assessment for fetal anomalies, including a fetal echocardiogram between weeks 16–18 of gestation, should be performed for women treated with lithium during the first trimester. In the event of unplanned conception during lithium therapy, the decision to continue or discontinue lithium should also be informed by the severity and course of the patient's illness as well as the time point in gestation when the exposure comes to attention. Discontinuing lithium therapy after cardiogenesis is complete at approximately 9–11 weeks gestation may be ill advised.

In addition to the developmental consequences of exposure, lithium's low therapeutic index also raises concerns regarding acute perinatal toxicities. Lithium exposure later in gestation can produce fetal and neonatal cardiac arrhythmias (N. Wilson et al. 1983), hypoglycemia and nephrogenic diabetes insipidus (Mizrahi et al. 1979), reversible changes in thyroid function (Karlsson et al. 1975), polyhydramnios, premature delivery, and a "floppy infant syndrome" similar to that witnessed with benzodiazepine exposure (Llewellyn et al. 1998). The neonate may exhibit signs of lithium toxicity at serum concentrations lower than maternal concentrations. Neonatal symptoms of lithium toxicity, including flaccidity, lethargy, and poor suck reflexes, may persist for more than 7 days (Woody et al. 1971).

In a pooled analysis of lithium placental passage and neonatal outcomes (Newport et al. 2005), we determined that 1) higher neonatal lithium concentrations were associated with significantly lower Apgar scores, longer hospital stays, and higher rates of CNS and neuromuscular complications; 2) umbilical cord (i.e., fetal) plasma concentrations were uniformly equivalent to maternal concentrations, suggesting that lithium rapidly equilibrates across the placenta; and 3) withholding lithium therapy for 24–48 hours prior to delivery resulted in a 0.28 mEq/L reduction in maternal (and presumably fetal) lithium concentrations, thereby likely improving neonatal outcomes. Consequently, scheduled deliveries, which afford opportunity for temporary suspension of lithium therapy for 24–48 hours, are advised for women taking lithium during late gestation.

The physiological alterations of pregnancy are of particular importance in the perinatal management of lithium. Changes in renal clearance across pregnancy and the potential for abrupt volume changes during delivery due to copious diaphoresis and the loss of blood and amniotic fluid mandate careful monitoring of lithium levels during pregnancy and especially at delivery. Furthermore, nonsteroidal anti-inflammatory drugs, which inhibit renal clearance of lithium, should be avoided in mother and infant alike during the early postpartum period.

The existing database regarding lithium and lactation encompasses 21 maternal–infant nursing dyads (Fries 1970; Schou and Amdisen 1973; Skausig and Schou 1977; Sykes et al. 1976; Tunnessen and Hertz 1972; Viguera et al. 2007; Weinstein and Goldfield 1969; Woody et al. 1971). Adverse events, including lethargy, hypotonia, hypothermia, cyanosis, electrocardiogram changes, and elevated thyroid-stimulating hormone level, were reported in 4 (19%) of these children (Skausig and Schou 1977; Tunnessen and Hertz 1972; Viguera et al. 2007; Woody et al. 1971), including 1 infant who developed frank lithium toxicity with a serum concentration of 1.4 mEq/L, which was double the maternal level (Skausig and Schou 1977). The American Academy of Pediatrics (2001) discourages the use of lithium during lactation. The largest pharmacokinetic study of lithium in lactation demonstrated a milk-to-plasma ratio of 0.53 and an infant-to-maternal plasma ratio of 0.24 (Viguera et al. 2007). In other studies, nursing infants have exhibited lithium concentrations generally ranging from 5% to 65% of maternal levels (Fries 1970; Kirksey and Groziak 1984; Schou and Amdisen 1973; Sykes et al. 1976; Tunnessen and Hertz 1972; Weinstein and Goldfield 1969), excluding the lone infant whose serum concentration was 200% of the maternal concentration (Skausig and Schou 1977). Because dehydration can increase the vulnerability to lithium toxicity, the hydration status of nursing infants of mothers taking lithium should be carefully monitored (Llewellyn et al. 1998). There are no available reports regarding the long-term neurobehavioral sequelae of lithium exposure during lactation.

Valproate (Valproic Acid)

Several anticonvulsants, including valproate, lamotrigine, and carbamazepine, are now used in the treatment of bipolar disorder. The widespread use of valproate raises serious concerns for the reproductive safety of women with bipolar disorder. Prenatal exposure to valproate has been associated with numerous congenital malformations, including neural tube defects (Bjerkedal et al. 1982; Centers for Disease Control 1992; Jager-Roman et al. 1986; Lindhout and Schmidt 1986); craniofacial anomalies, including craniosynostosis (Assencio-Ferreira et al. 2001; Lajeunie et al. 1998, 2001; Paulson and Paulson 1981); limb abnormalities (Rodriguez-Pinilla et al. 2000); and cardiovascular anomalies (Dalens et al. 1980; Koch et al. 1983; Sodhi et al. 2001).

Valproate exposure prior to neural tube closure, during the fourth week of gestation, confers a 1%–2% risk for spina bifida, which is 10–20 times greater than the prevalence in the general population (Bjerkedal et al. 1982; Centers for Disease Control 1992; Rosa 1991). One meta-analysis placed the risk for neural tube defects even higher, at 3.8%, with particular vulnerability for the infants of women whose daily dose exceeds 1,000 mg (Samrén et al. 1997). Other studies support this dose–response relationship (Canger et al. 1999; Kaneko et al. 1999; Omtzigt et al. 1992; Samrén et al. 1999), leading one group to recommend that daily dosages not exceed a maximum of 1,000 mg and that maternal serum concentrations not exceed a maximum of 70 µg/mL to reduce the risk for malformations (Kaneko et al. 1999). In a case–control study examining the incidence of limb malformations in a cohort of more than 44,000 children, 67 of whom were exposed to valproate in the first trimester, Rodriguez-Pinilla et al. (2000) reported an odds ratio of 6.17 for limb abnormalities among children exposed to valproate and estimated the risk of limb abnormalities from valproate exposure at 0.42%.

A *fetal valproate syndrome* was initially reported by Di Liberti et al. (1984) and subsequently confirmed by other investigators (Ardinger et al. 1988; Martinez-Frias 1990; Winter et al. 1987). The

phenotypic attributes of fetal valproate syndrome include stereotypical facial features such as bifrontal narrowing, midface hypoplasia, a broad nasal bridge, a short nose with anteverted nares, epicanthal folds, micrognathia, a shallow philtrum, a thin upper lip, and a thick lower lip (McMahon and Braddock 2001; S. J. Moore et al. 2000). Many of the congenital malformations previously associated with valproate exposure, including neural tube defects, congenital heart defects, cleft lip, cleft palate, limb abnormalities, urogenital defects, and abdominal wall defects, have been recognized as components of the fetal valproate syndrome (McMahon and Braddock 2001). Whereas the association between neural tube defects and folate deficiency is well established, valproate's antagonistic effect on folate may also underlie the full spectrum of fetal valproate syndrome. A case–control study comparing 57 children with fetal anticonvulsant syndromes, 46 of whose mothers were treated with valproate, with 152 control children found a significantly higher rate of a homozygosity for a mutation in the gene for methylenetetrahydrofolate reductase (MTHFR), a key enzyme in folate metabolism (Dean et al. 1999).

Neurodevelopmental outcomes associated with prenatal valproate exposure are equally concerning. A review indicated that developmental delay is evident in 20% and mental retardation in 10% of children exposed to valproate monotherapy prenatally (Kozma 2001). An interim report from a prospective multicenter investigation of the neurodevelopmental effects of prenatal antiepileptic drug exposure indicated that 24% of 2-year-olds with prenatal valproate exposure had mental developmental indexes of less than 70, more than doubling the rate of other antiepileptic drugs (Meador et al. 2006). Retrospective reports indicate that varying degrees of cognitive impairment may be present in children manifesting the physical sequelae of fetal valproate syndrome (Adab et al. 2001; Gaily et al. 1990; S. J. Moore et al. 2000). Fetal valproate syndrome has also been associated with pervasive developmental disorders, including autism (Bescoby-Chambers et al. 2001; S. J. Moore et al. 2000; G. Williams et al. 2001; P. G. Williams and Hersh 1997) and Asperger's syndrome (S. J. Moore et al. 2000).

Valproate exposure during gestation is also associated with risks for numerous fetal and neonatal toxicities, including hepatotoxicity (Kennedy and Koren 1998), coagulopathies (Mountain et al. 1970), and neonatal hypoglycemia (Ebbesen et al. 2000; Thisted and Ebbesen 1993). Ten of 13 infants who demonstrated neonatal hypoglycemia after prenatal valproate exposure developed withdrawal symptoms—including irritability, jitteriness, hypertonia, seizures, and vomiting—that began 12–24 hours after delivery and lasted up to 1 week (Ebbesen et al. 2000).

Pharmacokinetic studies in women with epilepsy indicate that maternal valproate concentrations steadily decline across pregnancy, reaching levels up to 50% lower than preconception concentrations (Yerby et al. 1990, 1992). Consistent findings from other studies demonstrate that valproate is more rapidly cleared during gestation, and especially during the final month of pregnancy (Nau et al. 1982b; Otani 1985; Philbert et al. 1985). Dosage increases during pregnancy may therefore be required to maintain therapeutic concentrations. Valproate readily crosses the human placenta, with fetal concentrations at delivery equal to or slightly higher than maternal concentrations (Froescher et al. 1984b; Philbert et al. 1985; Yerby et al. 1990, 1992).

The published literature regarding valproate and lactation includes 41 mother–infant nursing dyads (Alexander 1979; Bardy et al. 1982a; Dickinson et al. 1979; Froescher et al. 1981; Nau et al. 1981; Piontek et al. 2000; Stahl et al. 1997; Tsuru et al. 1988; von Unruh et al. 1984; Wisner and Perel 1998). From these cases, only one adverse event, thrombocytopenia and anemia in an infant, has been reported (Stahl et al. 1997). The pharmacokinetic data indicate that valproate milk-to-plasma ratios are uniformly low and that serum concentrations of nursing infants are 2%–40% of maternal concentrations (Alexander 1979; Bardy et al. 1982a; Piontek et al. 2000; Stahl et al. 1997; von Unruh et al. 1984; Wisner et al. 1996b). Studies of the neurobehavioral effects of valproate exposure during lactation have not been conducted.

In summary, among all psychotropic agents, valproate bears the greatest burden for fetal risk, leading the principal investigator of the multicenter Neurodevelopmental Effects of Antiepileptic Drugs study, Kimford Meador, M.D., to conclude that it "should never be used as a first-line choice in women of childbearing age" (Cassels 2006). If valproate must be used during pregnancy, its risk may be reduced by being careful not to exceed 1,000 mg per day or a serum concentration of 70 μg/ml. Folate supplementation (4–5 mg per day) is also recommended, although there is no evidence that this reduces the risk of valproate-associated anomalies. Because nearly half of pregnancies in the United States are unplanned, and women with unplanned pregnancies typically first recognize that they are pregnant during the sixth week of gestation or even later (2 full weeks after neural tube closure), all women of childbearing potential who are treated with valproate should receive concomitant folate supplementation, regardless of whether they plan to conceive. The preliminary evidence that aspects of fetal valproate syndrome other than neural tube defects may be associated with valproate's antagonism of folate metabolism suggests that folate supplementation should be administered not only in the first trimester but also throughout gestation. Because of the potential for valproate-associated neonatal coagulopathies, oral vitamin K supplementation (10–20 mg per day) may be considered during the final month of gestation. Prenatal surveillance for congenital abnormalities should include maternal serum α-fetoprotein, fetal echocardiography, and a level 2 ultrasound at approximately 16–18 weeks' gestation. Finally, genetic screening of women taking valproate for mutations in the MTHFR gene warrants future consideration but cannot yet be recommended for routine clinical practice.

In contrast to the marked risks of its use during pregnancy, valproate therapy during lactation appears to be well tolerated by nursing infants. Nevertheless, periodic assays of platelet count and serum liver enzymes of nursing infants are recommended because of the risks for thrombocytopenia and hepatotoxicity associated with valproate therapy.

Carbamazepine

Carbamazepine is associated with many of the same risks as valproate during gestation, although in many cases with less frequency or severity. For example, first-trimester carbamazepine exposure is associated with a risk for neural tube defects, although the 0.5%–1.0% risk in carbamazepine-exposed infants (Rosa 1991) is approximately half that seen with valproate exposure (Lindhout and Schmidt 1986; Rosa 1991). A meta-analysis of five prospective studies encompassing 1,255 prenatal exposures indicated that carbamazepine exposure in utero is associated with an increased risk of neural tube defects, cleft palate, cardiovascular abnormalities, and urinary tract anomalies (Matalon et al. 2002). An epidemiological study indicated that periconceptional folate supplementation was associated with a lower rate of neural tube defects among the children of women taking carbamazepine during pregnancy (Hernandez-Diaz et al. 2001).

A *fetal carbamazepine syndrome* manifested by a short nose, long philtrum, epicanthal folds, hypertelorism, upslanting palpebral fissures, and fingernail hypoplasia has also been described (Jones et al. 1989) but has received considerably less attention than fetal valproate syndrome. A subsequent study found the phenotypic characteristics of fetal carbamazepine syndrome evident in 6 of 47 children exposed to carbamazepine monotherapy during gestation (Ornoy and Cohen 1996). Other investigations have confirmed this association with facial anomalies (S. J. Moore et al. 2000; Nulman et al. 1997b; Scolnick et al. 1994; Wide et al. 2000), but one of these studies demonstrated similar facial abnormalities among children born to women with epilepsy who were untreated during pregnancy (Nulman et al. 1997b). This fetal carbamazepine syndrome has also been associated with developmental delay in up to 20% of exposed children (Jones et al. 1989; S. J. Moore et al. 2000; Ornoy and Cohen 1996), although other investigators have failed to demonstrate evidence of cognitive dysfunction in carbamazepine-exposed children (Gaily et al. 1990, 2004; Meador et al. 2006; Scolnick et al. 1994; van der Pol 1991; Wide et al. 2000).

Potential fetal/neonatal toxicities associated with carbamazepine exposure include blood dyscrasias, coagulopathies, skin reactions, and hepatotoxicity. Most of these risks remain theoretical, although neonatal hepatotoxicity has been reported in a carbamazepine-exposed infant (Frey et al. 2002).

Pharmacokinetic studies of carbamazepine clearance during gestation have yielded mixed results. Some investigators have reported statistically significant increases in carbamazepine clearance during the third trimester (Battino et al. 1982; Dam et al. 1979; Lander et al. 1980), but others have found no changes in carbamazepine clearance (Bardy et al. 1982b; Otani 1985; Yerby et al. 1985). Placental pharmacokinetic studies indicate that the placental transfer of carbamazepine is lower than that of other anticonvulsants (Nau et al. 1982a; Yerby et al. 1990, 1992), with fetal-to-maternal plasma ratios equaling 0.5–0.8 (Nau et al. 1982a).

The literature on carbamazepine and lactation includes 12 published reports and 144 mother–infant nursing pairs (Brent and Wisner 1998; Frey et al. 1990, 2002; Froescher et al. 1984a; Kaneko et al. 1982; Kok et al. 1982; Kuhnz et al. 1983; Merlob et al. 1992; Niebyl et al. 1979; Pynnonen and Sillanpaa 1975; Pynnonen et al. 1977; Wisner and Perel 1998), representing the most extensive data set for any mood stabilizer in lactation. This includes 8 reports of adverse events: 1 drowsy, irritable infant with an undetectable serum concentration of carbamazepine (Kok et al. 1982); 2 "hyperexcitable" infants in whom carbamazepine levels were not reported (Kuhnz et al. 1983); 2 infants with cholestatic hepatitis in whom carbamazepine levels were not reported (Frey et al. 1990, 2002); 1 infant with poor nursing effort (Froescher et al. 1984a); 1 infant with an increased serum concentration of γ-glutamyl transpeptidase (GGT) but no overt clinical sequelae whose serum concentration was 33% of the maternal concentration (Merlob et al. 1992); and 1 infant with a "seizurelike" phenomenon whose carbamazepine level was 8% of the maternal level (Brent and Wisner 1998). Serum carbamazepine concentrations in the 8 nursing infants in whom these levels were assessed ranged from undetectable to 65% of the maternal level (Brent and Wisner 1998; Kok et al. 1982; Merlob et al. 1992; Pynnonen and Sillanpaa 1975; Pynnonen et al. 1977; Wisner and Perel 1998).

Although the risks associated with in utero carbamazepine exposure are marginally better than those for valproate exposure, the clinical recommendations are quite similar. Carbamazepine should be avoided in pregnancy, especially during the first trimester. Folate supplementation (4–5 mg/day) is also recommended not only during gestation but also throughout the reproductive years because of the high prevalence of inadvertent conception in the United States. Women taking carbamazepine during gestation should receive prenatal surveillance for congenital abnormalities, including maternal serum α-fetoprotein, fetal echocardiography, and a level 2 ultrasound at approximately 16–18 weeks' gestation. Carbamazepine has by far the most extensive database for mood stabilizers in lactation, but reports of hepatic dysfunction in nursing infants certainly raise concern. Periodic assays of blood counts and serum liver enzymes of nursing infants are recommended in light of the risks for blood dyscrasias and hepatotoxicity associated with carbamazepine therapy.

Lamotrigine

Reproductive safety data regarding lamotrigine have rapidly accrued during the past decade and compare favorably with safety data for other agents available in the treatment of bipolar disorder. The overall risk of major fetal malformations following first-trimester prenatal exposure to lamotrigine is 2.6% (83 per 3,176 exposures, including 0.32% [8 per 2,537 exposures] for midline cleft formations) (Dominguez-Salgado et al. 2004; GlaxoSmithKline 2007; Holmes et al. 2006; Meador et al. 2006; Morrow et al. 2006; Sabers et al. 2004; Vajda et al. 2003), rates that are within the range of births not involving drug exposures. A recent report by the North American Pregnancy Registry (Holmes et al. 2006) noted a relatively high rate of midline facial clefts (0.89% of 564 exposures); however, the collective rate of orofacial clefts in the other registries was only 0.15% (2 per 1,937 exposures) (Dominguez-Salgado et al. 2004; GlaxoSmithKline 2007; Meador et al. 2006; Morrow et al. 2006;

Sabers et al. 2004; Vajda et al. 2003). Furthermore, a forthcoming case–control study by the European Surveillance of Congenital Anomalies (EUROCAT), encompassing 5,511 children with orofacial clefts and 80,052 children without clefts, reports an adjusted odds ratio of 0.67 for clefts with lamotrigine exposure (Dolk et al. 2008). The United Kingdom Epilepsy and Pregnancy Register reported a higher risk of malformations at maternal daily doses exceeding 200 mg (Morrow et al. 2006), although this was not confirmed in a subsequent analysis of the manufacturer's registry (GlaxoSmithKline 2007). Despite these reassuring findings, folate supplementation is recommended for all women of childbearing age taking any antiepileptic drug, including lamotrigine. Prospective neurodevelopmental data have also been favorable among children with prenatal lamotrigine exposure (Meador et al. 2006).

The pharmacokinetics of lamotrigine during pregnancy are well studied, with numerous studies consistently reporting that lamotrigine clearance steadily increases across gestation (de Haan et al. 2004; Pennell et al. 2004; Petrenaite et al. 2005; Tran et al. 2002). Indeed, seizure control in pregnant women with epilepsy can be maximized by regular monitoring of plasma concentrations and periodic dose changes as necessary (Pennell et al. 2008). These studies are limited by the cotherapy of lamotrigine with other anticonvulsants, which are known to alter the metabolism of lamotrigine. It is unclear whether similar dose changes would be necessary to maintain mood stability in patients with bipolar disorder and whether the common adjunctive agents used to treat bipolar disorder would have similar effects on lamotrigine metabolism. Studies in epilepsy patients taking lamotrigine also reveal that its rate of clearance abruptly declines after delivery (I. Ohman et al. 2000; Pennell et al. 2004; Tran et al. 2002). Therefore, dosage reductions may be necessary after delivery to avoid maternal symptoms of lamotrigine toxicity, such as dizziness, nausea and vomiting, and diplopia (Tran et al. 2002).

Published reports are also available regarding the placental passage of lamotrigine with a series of small studies to indicate that lamotrigine concentrations in fetal circulation at delivery are equal to maternal concentrations (Myllynen et al. 2003; I. Ohman et al. 2000; Sathanandar et al. 2000; Tomson et al. 1997). There have been no reports of acute adverse events observed in neonates exposed to lamotrigine.

Reports regarding lamotrigine and lactation (GlaxoSmithKline 2007; Liporace et al. 2004; Newport et al. 2008b; I. Ohman et al. 2000; Page-Sharp et al. 2006; Rambeck et al. 1997; Tomson et al. 1997) collectively encompass 55 maternal–infant nursing dyads. There have been no adverse events observed in these breast-fed infants, although 7 infants were observed to have a benign thrombocytosis (Newport et al. 2008a). In the largest (n = 30) of these studies (Newport et al. 2008a), the mean milk-to-plasma ratio was 41.3%, the relative infant dose equaled 9.2%, and the infant-to-maternal plasma ratio equaled 18.3%. Long-term neurobehavioral outcomes have not been studied in nursing infants exposed to lamotrigine.

Other Anticonvulsants

Other antiepileptic drugs (gabapentin, levetiracetam, zonisamide) may be utilized in the treatment of mental illnesses, although efficacy trials for these agents have not been impressive.

Clinicians should be aware that more pharmaceutical companies are initiating postmarketing surveillance registries for antiepileptic drugs.

Second-Generation Antipsychotics

The older first-generation antipsychotics (FGAs) such as haloperidol and chlorpromazine have historically been used to manage the agitated behavior that often accompanies a manic episode; however, these agents are not effective mood stabilizers. Recent interest has focused on the mood-stabilizing utility of the SGAs (i.e., aripiprazole, clozapine, olanzapine, paliperidone, quetiapine,

risperidone, and ziprasidone). With the exception of the newest of these agents, paliperidone, all SGAs now carry an FDA indication for one or more phases of bipolar disorder management.

The reproductive safety database for the SGAs, which is reviewed in the following section, contains scant data. Given this paucity of information, the SGAs cannot yet be recommended as first-line agents for the management of bipolar disorder during the peripartum. However, a risk–benefit assessment after inadvertent conception by a patient who is taking an SGA to manage bipolar disorder may indicate that continuing the SGA is preferable to switching to another mood stabilizer.

ANTIPSYCHOTICS

Second-Generation Antipsychotics

The advent of SSRIs in the 1980s revolutionized the treatment of depression, and a similar revolution has now taken place in the treatment of psychosis. The psychopharmacological armamentarium available to treat psychotic disorders has expanded beyond the traditional FGAs (e.g., haloperidol, chlorpromazine) to include a growing array of SGAs.

Commonly prescribed antipsychotic medications, as well as agents used to treat the side effects of FGAs, are listed in Table 64–5. The SGAs currently available in the United States are aripiprazole, clozapine, olanzapine, paliperidone, quetiapine, risperidone, and ziprasidone. Compared with the older FGAs, these new agents are less likely to produce tardive dyskinesia and extrapyramidal side effects (EPS) and arguably more effective in managing the negative symptoms of schizophrenia. The SGAs have consequently supplanted the FGAs as first-line medications for psychotic disorders and are being increasingly used for other psychiatric indications, including bipolar disorder, OCD, and treatment-resistant depression. Despite these agents' rapidly expanding use, the reproductive safety database regarding SGAs remains extremely limited.

TABLE 64–5. Antipsychotic medications

Generic name	Trade name	Daily dosage (mg/day)[a]	Risk category[b]	American Academy of Pediatrics rating[c]
First-generation antipsychotics				
Chlorpromazine	Thorazine	200–800	C	Unknown, but of concern
Fluphenazine	Prolixin	5–10	C	N/A
Haloperidol	Haldol	5–10	C_m	Unknown, but of concern
Loxapine	Loxitane	20–80	C	N/A
Mesoridazine	Serentil	100–400	C	Unknown, but of concern
Molindone	Moban	20–80	C	N/A
Perphenazine	Trilafon	8–32	C	Unknown, but of concern
Pimozide[d]	Orap	1–10	C	N/A
Thioridazine	Mellaril	200–600	C	N/A
Thiothixene	Navane	10–40	C	N/A
Trifluoperazine	Stelazine	10–40	C	Unknown, but of concern
Second-generation antipsychotics

Clozapine

The extant literature regarding the reproductive safety of clozapine, the oldest of the SGAs, is limited to case reports (Barnas et al. 1994; Di Michele et al. 1996; Kornhuber and Weller 1991; Waldman and Safferman 1993), case series (McKenna et al. 2005; Stoner et al. 1997; Tenyi and Tixler 1998), and a retrospective review (Dev and Krupp 1995), collectively encompassing 79 children exposed to clozapine during pregnancy and/or lactation. Adverse sequelae associated with perinatal clozapine therapy include maternal gestational diabetes (Dickson and Hogg 1998); several minor anomalies, including cephalohematoma, hyperpigmentation folds, and a coccygeal dimple, in an infant (Stoner et al. 1997); transient low-grade fever at delivery in an infant whose was mother receiving lithium cotherapy (Stoner et al. 1997); and floppy infant syndrome in a newborn whose mother was taking clozapine and lorazepam during gestation (Di Michele et al. 1996). In a review of 61 children exposed to clozapine perinatally, Dev and Krupp (1995) reported 5 cases of congenital malformations and 5 cases of neonatal syndromes, although many of these mothers were taking other psychotropic medications during pregnancy. The lone case report of clozapine use during lactation reported no adverse impact on the nursing infant (Kornhuber and Weller 1991).

The only investigation of the perinatal pharmacokinetics of clozapine demonstrated similar medication concentrations in maternal serum and amniotic fluid but markedly higher concentrations in fetal serum and breast milk (Barnas et al. 1994), leading the authors to conclude that clozapine accumulates in the fetal circulation and breast milk. Although no cases of agranulocytosis have been reported in infants of women taking clozapine during pregnancy or lactation, this theoretical risk and

the consequent requirement for monitoring of leukocyte counts in newborns and nursing infants limit the utility of clozapine during the peripartum.

Olanzapine

Of the remaining SGAs, the earliest reproductive safety data were reported for olanzapine. A published birth registry of 23 prospectively ascertained olanzapine-exposed pregnancies and 2 retrospectively ascertained cases of olanzapine lactation exposure from the Lilly Worldwide Pharmacovigilance Safety Database reported no major congenital malformations, 13% spontaneous abortions, 5% preterm deliveries, and 5% rate of fetal demise (Goldstein et al. 2000). A prospective study comparing outcomes among 151 pregnant women with SGA exposure (olanzapine, $n = 60$; risperidone, $n = 49$; quetiapine, $n = 36$; clozapine, $n = 6$) to 151 pregnant control subjects reported no differences in rates of spontaneous abortion, stillbirth, major malformations, prematurity, or low birth weight (McKenna et al. 2005). In this study, only one SGA-exposed child (olanzapine) was observed to have any major malformations (a series of midline defects including an oral cleft, encephalocele, and aqueductal stenosis).

In a recent study of antipsychotic placental passage rates and neonatal outcomes (Newport et al. 2007), umbilical cord concentrations in olanzapine-exposed neonates ($n = 14$) were 72.1% of maternal concentrations (higher than rates for haloperidol, risperidone, and quetiapine). In this study, there were trends toward higher rates of low birth weight (30.8%; $P < 0.06$) and neonatal intensive care unit admission (30.8%; $P < 0.09$) among neonates exposed to olanzapine than those exposed to the other agents.

Case reports of 16 infants exposed to olanzapine during lactation with no evidence of infant toxicity currently appear in the literature (Croke et al. 2002; Friedman and Rosenthal 2003; Gardiner et al. 2003; Goldstein et al. 2000; Kirchheiner et al. 2000). Pharmacokinetic studies of olanzapine exposure during lactation have reported that plasma concentrations were undetectable in infants during nursing (Gardiner et al. 2003; Kirchheiner et al. 2000) and that the median infant daily dose via breast-feeding was approximately 1.0%–1.6% of the maternal dose (Ambresin et al. 2004; Croke et al. 2002; Gardiner et al. 2003).

There are no available data regarding the neurodevelopmental effects of olanzapine exposure during pregnancy or lactation.

Risperidone

There are two prospective reports of pregnancy outcome for women with first-trimester risperidone exposure. In the first, an assessment of the collective outcomes for several SGAs (McKenna et al. 2005) included 49 women with risperidone exposure. There were no children born with major malformations in this sample. The second study, including 68 women with first-trimester exposure and known outcomes, reported 9 (13.2%) spontaneous abortions, 1 (1.5%) stillbirth, and 2 (2.9%) children with major malformations (Coppola et al. 2007). The reproductive safety literature for risperidone encompasses 49 women and is limited to a single case report.

In our recent analysis of antipsychotic placental passage, risperidone concentrations in neonates ($n = 6$) were 49.2% of maternal levels (Newport et al. 2007). Pharmacokinetic studies of risperidone excretion into breast milk have reported milk-to-plasma ratios of less than 0.5 for both risperidone and 9-hydroxyrisperidone (R. C. Hill et al. 2000; Ilett et al. 2004) and infant doses ranging from 2.3% to 4.7% of the maternal dose (Ilett et al. 2004).

There are no available data regarding the neurodevelopmental effects of risperidone exposure during pregnancy or lactation.

Quetiapine

The reproductive safety literature for first-trimester quetiapine exposure is limited to the McKenna et al. (2005) study, which reported no major malformations among 36 infants exposed to quetiapine. In the Newport et al. (2007) study of antipsychotic placental passage, quetiapine concentrations among neonates (*n* = 21) were 23% of maternal concentrations. To our knowledge, this is the lowest placental passage rate ever reported for a psychotropic agent.

A single case of quetiapine use during lactation following use during pregnancy estimated the nursing infant dose at 0.09% of the maternal daily dose (Lee et al. 2004).

There are no available data regarding the neurodevelopmental effects of quetiapine exposure during pregnancy or lactation.

Aripiprazole

There are currently no reports regarding the use of aripiprazole during pregnancy or lactation.

Paliperidone

There are currently no reports regarding the use of paliperidone during pregnancy or lactation.

Ziprasidone

There are currently no reports regarding the use of ziprasidone during pregnancy or lactation.

First-Generation Antipsychotics

In contrast to the SGAs and most other classes of psychotropic medications, the FGAs have a large reproductive safety database that addresses concerns of both somatic and neurobehavioral teratogenicity. Furthermore, the widespread use of phenothiazines to treat pregnancy-associated emesis (typically at low doses) aids in separating the effects of psychiatric illness and antipsychotic drugs on pregnancy outcome. Chlorpromazine, haloperidol, and perphenazine have received the greatest scrutiny, with no significant associations between these compounds and major congenital malformations forthcoming (Goldberg and DiMascio 1978; R. M. Hill and Stern 1979; Nurnberg and Prudic 1984).

In a study of 100 women treated with haloperidol (mean dosage = 1.2 mg/day) for hyperemesis gravidarum, no differences in gestational duration, fetal viability, or birth weight were noted (Van Waes and Van de Velde 1969). In a large prospective study encompassing nearly 20,000 women treated primarily with phenothiazines for emesis, Milkovich and Van den Berg (1976) found no significant association with neonatal survival rates or severe anomalies after controlling for maternal age, medication, and gestational age at exposure. Similar results have been obtained in several retrospective studies of women treated with trifluoperazine for repeated abortions and emesis (Moriarty and Nance 1963; Rawlings et al. 1963). In contrast, Rumeau-Rouquette et al. (1977) reported a significant association of major anomalies with prenatal exposure to aliphatic side-chain phenothiazines but not with piperazine- or piperidine-class agents. Reanalysis of the data obtained by Milkovich and Van den Berg (1976) did find a significant risk of malformations associated with phenothiazine exposure in weeks 4 through 10 of gestation (Edlund and Craig 1976).

Clinical neurobehavioral outcome studies encompassing 203 children exposed to FGAs during gestation detected no significant differences in IQ scores at 4 years of age (Kris 1965; Slone et al. 1977), although relatively low antipsychotic doses were used by many women in these studies. Conversely, several laboratory animal studies (Hoffeld et al. 1968; Ordy et al. 1966; Robertson et al. 1980), although not all (Dallemagne and Weiss 1982), have demonstrated persistent deficits in learning and memory among offspring prenatally exposed to FGA medications.

Beyond the teratogenic potential of the FGAs lies the possibility of fetal and infant toxicities such as neuroleptic malignant syndrome (James 1988) and EPS manifested by heightened muscle tone and

increased rooting and tendon reflexes persisting for several months (Cleary 1977; R. M. Hill et al. 1966; M. O. O'Connor et al. 1981). Furthermore, prenatal exposure to SGAs has been reported to produce neonatal jaundice (Scokel and Jones 1962) and postnatal intestinal obstruction (Falterman and Richardson 1980).

In our recent study of antipsychotic placental passage, neonatal haloperidol (*n* = 13) concentrations were 66% of maternal concentrations (Newport et al. 2005).

In lactation, chlorpromazine is the most widely studied typical antipsychotic, with 7 infants exposed to chlorpromazine during nursing exhibiting no developmental deficits at 16-month and 5-year follow-up evaluations (Kris and Carmichael 1957). However, 3 infants in another study whose mothers were prescribed both chlorpromazine and haloperidol exhibited evidence of developmental delay at 12–18 months (Yoshida et al. 1998b). Pharmacokinetic investigations of FGAs during lactation, including haloperidol (Stewart et al. 1980; Whalley et al. 1981; Yoshida et al. 1998b), trifluoperazine (J. T. Wilson et al. 1980; Yoshida et al. 1998b), perphenazine (J. T. Wilson et al. 1980), thioxanthenes (Matheson and Skjaeraasen 1988), and chlorpromazine (Yoshida et al. 1998b), have uniformly reported milk-to-plasma ratios of less than 1, although adequate control for distribution and time gradients is lacking in these studies. One group postulated that the physicochemical properties of perphenazine could lead it to become "trapped" in breast milk (J. T. Wilson et al. 1980).

Fetal and infant exposure to any of the various agents available for the management of EPS (e.g., diphenhydramine, benztropine, amantadine) also raises concern. Results of the Collaborative Perinatal Project indicate that first-trimester exposure to diphenhydramine, the best studied of these medications, is associated with major and minor congenital anomalies (Miller 1991; Wisner and Perel 1988). A case–control study demonstrated a significantly higher rate of prenatal diphenhydramine exposure among 599 infants with oral clefts than among 590 control infants (Saxén 1974). Clinical studies of the teratogenic potential of benztropine and amantadine are lacking, although laboratory animal studies indicate that amantadine is associated with an elevated risk of congenital malformations (Hirsch and Swartz 1980). Perinatal toxicities, including neonatal intestinal obstruction after gestational exposure to benztropine (Falterman and Richardson 1980) and a possible neonatal diphenhydramine withdrawal syndrome manifested by tremulousness and diarrhea (Parkin 1974), also warrant concern.

In summary, FGAs have been widely used for almost 50 years, and the paucity of data linking these agents to either teratogenic or toxic effects suggests that the risk associated with these medications is minimal. In particular, piperazine phenothiazines (e.g., trifluoperazine, perphenazine) may have especially limited teratogenic potential (Rumeau-Rouquette et al. 1977). Given the greater perinatal risks associated with anticholinergic medications, their use should be avoided if possible. Consequently, FGAs used during the peripartum should be kept at the lowest effective dose to minimize the need for adjunctive medications to manage EPS.

Early data regarding the teratogenic potential of the SGAs have been reassuring; however, the limited volume of SGA data to date precludes definitive conclusions regarding their reproductive safety. Therefore, the routine use of SGAs during pregnancy and lactation cannot yet be recommended. Nonetheless, if a woman who is taking an SGA inadvertently conceives, a comprehensive risk–benefit assessment may indicate that continuing the SGA (to which the fetus has already been exposed) during gestation is preferable to switching to an FGA (to which the fetus has not yet been exposed). Monitoring of blood glucose and weight gain should be an integral aspect of clinical management during pregnancy.

ANXIOLYTICS

Benzodiazepines and antidepressants are the most commonly used medications for the treatment of anxiety disorders. Benzodiazepines have a wide spectrum of clinical indications, including the full

array of anxiety disorders, insomnia, alcohol detoxification, muscle relaxation, adjunctive treatment of seizure disorders, and conscious sedation during invasive medical procedures. A retrospective survey of Medicaid prescription records for more than 100,000 pregnant women between 1980 and 1983 found that at least 2% were prescribed a benzodiazepine during gestation (Bergman et al. 1992). Table 64–6 lists the benzodiazepine and nonbenzodiazepine anxiolytics and sedative-hypnotics used in the treatment of anxiety disorders and insomnia.

TABLE 64–6. Anxiolytic and hypnotic medications

Generic name	Trade name	Daily dosage (mg/day)[a]	Risk category[b]	American Academy of Pediatrics rating[c]
Benzodiazepines

[a]Dosing strategies adapted from Schatzberg and Cole 1991; Kaplan and Sadock 1993; and for newer medications, the manufacturers' package inserts.

[b]Risk category adapted from Briggs et al. 2005 and/or *Physicians' Desk Reference* 2007; "m" subscript indicates data taken from the manufacturer's package insert.

[c]American Academy of Pediatrics 2001.

[d]Not listed in Briggs et al. 1994. Risk category taken from *Physicians' Desk Reference* (1992, 1993, 1994, and 1996 editions).

The earliest studies of benzodiazepine-associated teratogenic effects reported an increased risk of oral clefts after in utero exposure to diazepam (Aarskog 1975; Saxén 1975; Saxén and Saxén 1974), but later studies failed to confirm this association (Entman and Vaughn 1984; Rosenberg et al. 1984; Shiono and Mills 1984). Prospective studies of first-trimester alprazolam exposure encompassing approximately 1,300 pregnancies demonstrated no excess of oral clefts or other congenital anomalies (Barry and St. Clair 1987; Schick-Boschetto and Zuber 1992; St. Clair and Schirmer 1992). A subsequent meta-analysis by Altshuler et al. (1996), which pooled data from several studies, demonstrated that prenatal benzodiazepine exposure does confer an increased risk of oral cleft, although the absolute risk increased by only 0.01%, from 6 in 10,000 to 7 in 10,000. This conclusion is consistent with the findings of a recent case–control study that reported no difference in the rate of prenatal benzodiazepine exposure between more than 38,000 infants with congenital anomalies and nearly 23,000 control children without congenital defects (Eros et al. 2002).

Longitudinal follow-up studies to evaluate the neurobehavioral effects of prenatal benzodiazepine exposure are urgently needed. A "benzodiazepine exposure syndrome," including growth retardation, dysmorphism, and both mental and psychomotor retardation in infants exposed prenatally to benzodiazepines (Laegreid et al. 1987), has been reported, although other investigators have disputed this finding (Gerhardsson and Alfredsson 1987; Winter 1987). A second group found no differences in the incidence of behavioral abnormalities at age 8 months or in IQ scores at age 4 years among children exposed to chlordiazepoxide during gestation (Hartz et al. 1975). Nevertheless, a series of laboratory animal studies continues to raise concerns that prenatal benzodiazepine exposure may be associated with long-term deficits in memory and learning ability (Frieder et al. 1984; Hassmannova and Myslivecek 1994; Myslivecek et al. 1991).

Although the data regarding the teratogenic effects of benzodiazepine exposure remain somewhat controversial, the occurrence of neonatal toxicity and withdrawal syndromes is well documented. Numerous groups have described a floppy infant syndrome characterized by hypothermia, lethargy, poor respiratory effort, and feeding difficulties after maternal use of benzodiazepines shortly before delivery (Erkkola et al. 1983; J. N. Fisher et al. 1985; Haram 1977; Kriel and Cloyd 1982; McAuley et al. 1982; Sanchis et al. 1991; Speight 1977; Woods and Malan 1978). In a study of 53 infants born to women who were administered lorazepam prior to delivery, term infants whose mothers had taken oral lorazepam (up to 2.5 mg three times daily) showed no evidence of toxicity other than a minimal delay in establishing feeding, but preterm infants and term infants whose mothers had received larger intravenous doses of lorazepam exhibited a constellation of symptoms consistent with floppy infant syndrome (Whitelaw et al. 1981). Neonatal withdrawal syndromes characterized by restlessness, hypertonia, hyperreflexia, tremulousness, apnea, diarrhea, and vomiting have been described in infants whose mothers were taking alprazolam (Barry and St. Clair 1987), chlordiazepoxide (Athinarayanan et al. 1976; Bitnum 1969; Stirrat et al. 1974), or diazepam (Backes and Cordero 1980; Mazzi 1977). Symptoms of these neonatal syndromes have been reported to persist for as long as 3 months after delivery (for a review, see Miller 1991).

Pharmacokinetic studies during pregnancy indicate that benzodiazepines as a class readily traverse the placenta and that some of these drugs may accumulate in the fetus after prolonged administration (Mandelli et al. 1975; Shannon et al. 1972). For example, the fetal–maternal ratio of plasma diazepam concentrations at delivery is generally greater than 1 (Erkkola et al. 1974), likely a result, at least in part, of the fact that the fetal rate of metabolizing diazepam is considerably slower than the adult rate (Mandelli et al. 1975). In addition, particularly high concentrations of diazepam are sequestered in lipophilic fetal tissues, including the fetal brain, lungs, and heart (Mandelli et al. 1975). A study reporting that fetal–maternal ratios of lorazepam are typically less than 1 (Whitelaw et al. 1981) suggests that placental transfer of lorazepam is lower than that of other benzodiazepines. Neonatal clearance of lorazepam is slow, with detectable levels evident 8 days after delivery (Whitelaw et al. 1981), and the clearance of chlordiazepoxide appears to be even slower (Athinarayanan et al. 1976).

Buist et al. (1990) concluded that benzodiazepines at relatively low doses present no contraindication to nursing. However, infants with an impaired capacity to metabolize benzodiazepines may exhibit sedation and poor feeding even with low maternal doses (Wesson et al. 1985). Overall, benzodiazepines exhibit lower milk-to-plasma ratios than other classes of psychotropics. For example, Wreitland (1987) found a milk-to-plasma ratio of 0.1–0.3 for oxazepam and calculated that the infant daily dose via lactation is 1/1,000 of the maternal dose. The percentage of the maternal dose of lorazepam to which a nursing infant is exposed has been estimated to be 2.2% (Summerfield and Nielsen 1985).

In summary, benzodiazepines do not appear to carry a significant risk of somatic teratogenesis, but neurobehavioral sequelae remain obscure. Because benzodiazepines are associated with a risk for neonatal toxicity and withdrawal syndromes, these drugs should be tapered prior to delivery when possible. Benzodiazepines should not, however, be abruptly withdrawn during pregnancy. Clonazepam (FDA Category C) appears to have minimal teratogenic risks (Sullivan and McElhatton 1977). Because lorazepam and oxazepam are less dependent on hepatic metabolism, they theoretically have less potential for fetal accumulation during pregnancy. Finally, when judicious doses are utilized, benzodiazepines can be safely administered during lactation. However, breast-feeding should be discontinued if an infant exhibits sedation or other signs of benzodiazepine toxicity, regardless of maternal dose.

Recently, newer agents, including buspirone, a nonbenzodiazepine anxiolytic, and zolpidem and zaleplon, nonbenzodiazepine hypnotics, have been added to the psychotropic armamentarium. There are no published reports of the use of these agents in pregnancy or lactation.

FUTURE DIRECTIONS AND GENERAL RECOMMENDATIONS

The development of treatment guidelines for mental illness during pregnancy and lactation continues to be hampered by the haphazard accrual of research data with inconsistent methodologies. Whereas there are limited clinical data to support the contention that most psychotropic medications are teratogenic, laboratory animal studies, which typically attain maternal concentrations markedly higher than those achieved in clinical care, demonstrate clear somatic and neurobehavioral teratogenic effects (Elia et al. 1987). Such discrepancies between the clinical and preclinical data hinder efforts to construct reliable treatment recommendations. Because pregnant and nursing women are generally excluded from clinical trials of pharmacological agents, definitive clarification is unlikely to be forthcoming in the near future.

This raises questions about the future of clinical research in pregnancy and lactation. Some investigators have argued that conducting clinical trials in pregnant and nursing women is on its face unethical (Kerns 1986). Although such a view is understandable, the failure to conduct such studies may deprive some women of available treatment and may over time increase the overall risk to women and their infants. Alternative ethical positions regarding perinatal clinical research have been raised. In an investigation of alternative interventions following evidence of in utero failure to thrive, obstetrical researchers have advocated application of the *uncertainty principle* (Peto and Baigent 1998) to the ethical question of clinical research during gestation (Vail et al. 2001). The uncertainty principle mandates that a patient, even a pregnant patient, should be ethically eligible to participate in a randomized clinical trial if the preferred clinical course of action is uncertain. Because the relative risks to fetus and infant of exposure to maternal psychiatric illness compared with exposure to maternal psychotropic medication are often unclear, the uncertainty principle may be equally applicable to the study of psychiatric treatment during pregnancy and lactation. These questions must be deliberated so that perinatal psychiatric research can be advanced in an ethically responsible, yet expeditious, manner.

Meanwhile, given the current state of our knowledge, a thorough risk–benefit analysis should be

completed for each woman presenting with concerns of psychiatric illness during pregnancy and lactation. This risk–benefit analysis should consider factors such as maternal psychiatric history, the potential deleterious effects of untreated illness on both the mother and her infant, and the potential adverse effects of offspring exposure to different classes of psychotropic medications within particular developmental windows. Table 64–7 and Table 64–8 summarize the basic risk–benefit assessments for pregnancy and lactation, which should be individualized according to the patient's history and treatment goals.

TABLE 64–7. Risk–benefit assessment for pregnancy: summary of facts

Known

85% of all pregnancies produce live births.

7%–14% of deliveries are preterm.

2%–4% of live births result in infants with significant malformations, and up to 12% have minor anomalies.

>60% of all women take at least one prescription medication during pregnancy.

In the ideal pregnancy, as defined by the Centers for Disease Control and Prevention, maternal weight is ±15% of ideal body weight, and the mother was taking prenatal vitamins with folic acid for 6 weeks before conception.

Most women learn of pregnancy at 5–8 weeks' gestation and therefore may be past the window of risk for fetal anomalies associated with psychotropic medications.

Pregnancy is not protective against psychiatric illness.

Increasing data

Major depressive episodes occur with similar incidence during pregnancy as during nongravid periods.

Obsessive-compulsive disorder may have its onset or may worsen during pregnancy.

The incidence of psychotic disorders varies throughout pregnancy; there are limited data suggesting a need to decrease dosage of antipsychotic medications.

The teratogenic risk of psychotropic medications has been historically overestimated.

Increasing data on obstetrical outcome and follow-up of infants of mothers taking psychotropic medications are comparable in study sample sizes to data on most other prescription drugs.

Untreated maternal mental illness may adversely affect obstetrical outcome and infant development.

Unknown

The long-term neurobehavioral effects of in utero exposure to psychotropic medications are unknown, although initial studies have not reported adverse effects for several medications.

TABLE 64–8. Risk–benefit assessment for lactation: summary of facts

Known: postpartum

>60% of women plan to breast-feed.

5%–17% of all nursing women take a prescription medication during breast-feeding.

12%–20% of nursing women smoke cigarettes.

Breast-feeding is supported by numerous professional organizations as the ideal form of nutrition for the infant.

The postnatal period is a high-risk time for onset or relapse of psychiatric illness.

All psychotropic medications studied to date are excreted in breast milk.

Increasing data

Untreated maternal mental illness has an adverse effect on mother–infant attachment and later infant development.

The adverse effects of psychotropic agents on infants are limited to case reports.

The nursing infant's daily dose of psychotropic agents is less than the maternal daily dose.

The nursing infant's exposure to psychotropic medications is less than the fetal exposure.

Psychotropic medications are excreted in breast milk with a specific individual time course, allowing the minimization of infant exposure with continuation of breast-feeding.

Unknown

The long-term neurobehavioral effects of infant exposure to psychotropic medications through breast-feeding are unknown.

Initial Treatment Approach for Women of Reproductive Age

When treating women of reproductive age, it is advisable to assume at all times that pregnancy is imminent. More than 50% of pregnancies in the United States are unplanned; however, it is not cost effective to screen for pregnancy at all routine outpatient psychiatric visits.

By factoring reproductive safety considerations into all treatment decisions for women of child-bearing age, whether or not the patient is pregnant or actively trying to conceive, clinicians can maximize reproductive safety when inadvertent conception occurs.

Assuming that the clinician has already exhausted reasonable nonpharmacological interventions, we offer the following general treatment recommendations for the care of a patient with a mental disorder during pregnancy and lactation.

Informed Consent

It is impossible to provide an exhaustive list of all the risks for any given psychotropic medication, but the evidence (or lack thereof) for adverse activational effects (e.g., toxicity, withdrawal) and organizational effects (e.g., somatic teratogenesis, neurobehavioral teratogenesis) of each medication should be reviewed. It is equally important to discuss with the patient the risks of the untreated illness to both the mother and the infant. Finally, it is important to document that other treatment modalities have been attempted or considered.

Choice of Medication

When the decision is made to use a psychotropic medication, the goal is to maximize efficacy so that offspring exposure to maternal mental illness can most reliably be eliminated while avoiding offspring exposure to multiple medications. The most important factor in choosing a medication is therefore treatment history. If a patient has a history of a positive response to a particular medication, a novel agent should not be started during pregnancy or lactation. Such an approach only increases the risk of offspring exposure to multiple medications and continued maternal illness. Prior offspring exposures also warrant consideration. If a patient was taking a particular medication earlier in gestation (and it was efficacious), continuing or restarting that medication is usually preferable to switching to a new medication. Switching medications in this manner automatically increases the child's number of medication exposures and may extend the duration of maternal illness. In addition to data from the treatment history, medications with the following characteristics should be sought:

- *Greatest reproductive safety database*—Medications with some published pregnancy and/or lactation safety data are preferred. Being the first to use a particular medication in pregnancy or nursing is not advisable. Medications that have been available for a longer time usually have a larger database.
- *Lower FDA risk category (B > C > D)*—The FDA is empirically conservative and has access to the greatest

amount of pre- and postmarketing data. Although this rating may be controversial for some medications, medicolegal considerations support this approach.

- *Few or no metabolites*—Data from both pregnancy and lactation suggest that drug metabolites, which typically have longer elimination half-lives relative to the parent drug, may achieve higher steady-state levels in both fetal circulation and nursing infant serum. The issue of active versus inactive metabolites is unresolved with respect to teratogenic effects.
- *Fewer side effects and drug interactions*—Medications with fewer hypotensive and anticholinergic side effects are preferable. Additionally, the effect on seizure threshold and potential interaction with commonly used obstetrical anesthetic and analgesic agents should be minimized.
- *Concordant data*—Medications with conflicting data should be avoided; a clinically comparable alternative should be used, if available. Adherence to this recommendation also should reduce any potential legal liability.

Dosage

The goal of treatment during pregnancy and lactation is adequate treatment for syndrome remission. Partial treatment only enhances risk by continuing to expose mother and infant to both illness and medications. The minimum effective dose should be maintained throughout treatment, and the clinician should remain mindful that dosage requirements might change during pregnancy. To minimize the potential for neonatal withdrawal and maternal toxicity after delivery, careful monitoring of side effects and serum concentrations may be indicated. Adjusting the feeding and dose schedule and discarding the peak breast milk concentrations for several agents can minimize exposure of nursing infants.

Communication With Other Physicians

It is highly recommended that the psychiatrist discuss the medication and potential interactions with both the patient's obstetrician and, if the patient chooses to nurse, her infant's pediatrician.

Monitoring Exposure of Nursing Infants

Most clinical laboratory assays lack the sensitivity necessary to detect the typical serum concentrations of nursing infants, and even detectable infant serum concentrations are uninterpretable; therefore, infant serum monitoring is not routinely indicated for most psychotropic medications. One noteworthy exception is the child who is exhibiting potential medication side effects. A small proportion of breast-feeding children may be metabolic outliers for a particular medication and thus may accumulate especially high serum concentrations. If there is a reasonable index of suspicion that the child's symptoms represent a medication effect, then breast-feeding should be discontinued, regardless of infant serum concentration. Consequently, we recommend checking an infant's serum concentration when the child is suspected to be experiencing a medication side effect. Furthermore, infant serum concentrations and other laboratory studies (e.g., blood counts, electrolytes, hepatic profiles) should be monitored when nursing mothers are taking medications (e.g., certain anticonvulsants) with low therapeutic indices or known systemic toxicities.

CONCLUSION

The use of pharmacological therapies during pregnancy and lactation will continue to be a complex clinical endeavor that will certainly generate anxiety among patients and clinicians. There is a propensity in the medical literature and the news media to emphasize adverse outcomes, whereas negative study results seldom garner much attention. This is true for both medication and illness exposures. Consequently, clinicians must practice with access to incomplete information.

Thoughtful consideration of "pregnancy potential" in the treatment planning for women of reproductive capacity serves to reduce the consternation precipitated by a positive pregnancy test. By inquiring routinely about birth control during all visits when treating women during the reproductive

years, clinicians can provide a conduit for discussion and treatment planning that aims to reduce risk for mother and child.

Chapter 65. Treatment During Late Life

TREATMENT DURING LATE LIFE: INTRODUCTION

Adverse events caused by medication have been estimated to be between the fourth and sixth leading cause of death in the United States (Lazarou et al. 1998). The elderly bear the greatest burden of medical illness and are subject to extensive medication regimens; in consequence, they experience more adverse drug events than do other segments of the population. In a large study of ambulatory Medicare enrollees, 38% of adverse drug events were serious, life-threatening, or fatal and 28% were considered preventable (Gurwitz et al. 2005). Moreover, psychotropics are among the most common medications associated with preventable adverse drug events in elderly patients in long-term care settings (Gurwitz et al. 2000).

PHARMACOKINETICS OF PSYCHOTROPIC MEDICATIONS IN THE ELDERLY

In general, age-associated pharmacokinetic changes result in higher and more variable drug concentrations. Nonetheless, specific information on the pharmacokinetics of most psychoactive medications is inadequate, particularly with regard to medical subgroups and potential drug interactions. The limited information that does exist for older subjects is largely derived from classical pharmacokinetic modeling (Pollock 2005). For example, with fluoxetine, the only published data on disposition in older subjects are limited to a study of single doses in 11 healthy volunteers (Bergstrom et al. 1988). Traditional pharmacokinetic studies require a large number of plasma drug samples obtained from a small number (i.e., 6–12) of volunteers. Single-dose pharmacokinetic studies usually are not adequate to rule out the possibility of nonlinear kinetics. Moreover, it is difficult to generalize from these studies because of the small numbers, the virtual absence of elderly subjects and those with illness, and the concurrent medication use typical at this age (DeVane and Pollock 1999). It should also be appreciated that age or illness-associated differences in pharmacodynamics are not interpretable in the absence of drug concentration data. Population pharmacokinetics provides a means for addressing heterogeneous drug exposure for elders using minimal sampling methods (Bigos et al. 2006). For example, using this approach, our laboratory analyzed 199 citalopram concentration samples obtained on clinic visits from 109 patients across a wide age range. After correcting for weight effects, a significant relationship between age and clearance was observed, with the clearance of citalopram decreasing from approximately 30 L/hour at 18 years of age to as low as 5 L/hour at 93 years of age (Bies et al. 2004). Similarly, among 171 elders treated with paroxetine, we found that weight, sex, and cytochrome P450 (CYP) 2D6 genotype had significant pharmacokinetic effects (Feng et al. 2006).

Although individuals older than 65 years now account for more than one-third of prescription drug expenditures in the United States, they are often excluded from clinical and regulatory trials (Atkin et al. 1999). While regulatory authorities have developed guidelines for pharmaceutical companies regarding new medications that are likely to have significant use in the elderly, the full impact of these guidelines has yet to be realized. In addition, the trials that do include elders rarely include the "oldest old" (i.e., 85+ years), those having multiple comorbidities, or those taking multiple medications. These exclusions raise questions about the generalizability of psychotropic data to the frail elderly. The lack of information on new pharmaceuticals has resulted in an escalating pattern of

recommended dosage decreases for neuropharmacological drugs after there has been clinical experience in older patients (Cross et al. 2002).

Age-associated pharmacokinetic differences may be due to changes in absorption, distribution, metabolism, or elimination of a drug (Table 65–1). The multidimensional changes associated with aging are heterogeneous, and only the most superficial generalizations can be made (Lotrich and Pollock 2005; Pollock 1998).

TABLE 65–1. Physiological changes in the elderly associated with altered pharmacokinetics

Organ system	Change	Pharmacokinetic consequence
Gastrointestinal tract	Decreased intestinal and splanchnic blood flow	Decreased rate of drug absorption
Circulatory	Decreased concentration of plasma albumin and increased α_1-acid glycoprotein	Increased or decreased free concentration of drugs in plasma
Kidney	Decreased glomerular filtration rate	Decreased renal clearance of active metabolites
Muscle	Decreased lean body mass and increased adipose tissue	Altered volume of distribution of lipid-soluble drugs, leading to increased elimination half-life
Liver	Decreased liver size; decreased hepatic blood flow; minimal effects on cytochrome P450 enzyme activity	Decreased hepatic clearance

Absorption

Absorption of nutrients, such as iron, thiamine, and calcium, is often impaired in the elderly. Nonetheless, the rate and extent of passive drug absorption do not appear to be affected by normal aging. Antacids, high-fiber supplements, and cholestyramine may significantly diminish the absorption of medications.

Distribution

For most psychotropics that are lipid soluble, the loss of lean body mass with aging will lead to increases in their volumes of distribution, resulting in longer half-lives and drug accumulation. This is because a drug's half-life is directly proportional to its apparent volume of distribution. Conversely, for water-soluble drugs such as lithium and digoxin, volumes of distribution will be diminished in older patients, reducing the margin of safety after acute increases in plasma drug concentration.

Reductions in serum albumin with age and possible increases in α_1-acid glycoprotein with illness may affect the extent of drug bound to plasma proteins. However, it is now recognized that changes in plasma protein binding are of clinical significance only when therapeutic drug monitoring is used to adjust dosing, because total drug concentrations (free + protein bound) are usually reported (Benet and Hoener 2002). Total drug levels may be interpreted as too low if a drug's free fraction is increased by diminished plasma proteins or drug displacement. The use of free drug levels in older patients has been found to be useful for lidocaine, theophylline, phenytoin, and digitoxin. More data regarding the use of therapeutic plasma levels are needed for elders treated with valproate, given its greater risks for thrombocytopenia and hepatotoxicity in the aged (Conley et al. 2001).

Metabolism

Available evidence suggests that there is no uniform age-associated decline in liver metabolism by CYP enzymes (Pollock et al. 1992b; Schmucker 2001). Nonetheless, reductions in hepatic mass and

blood flow with aging place greater emphasis on interindividual differences in drug metabolic capacity. These metabolic differences may be either genetic or the result of interactions from multiple medications. Enzyme specificity suggests that inhibition or induction of a given CYP enzyme will affect all drugs metabolized by that specific enzyme (Pollock 1998).

CYP2D6 is the enzyme responsible for metabolizing tricyclic antidepressants (TCAs) and venlafaxine as well as several older neuroleptics and risperidone. Among the white population, 5%–10% are genetically poor CYP2D6 metabolizers, which has been shown in older patients to affect nortriptyline doses (Murphy et al. 2001) and the severity of perphenazine-associated adverse effects (Pollock et al. 1995). Concern also has been raised about poor CYP2D6 metabolizers treated with venlafaxine or extensive metabolizers given venlafaxine and concomitant 2D6 inhibitors (Johnson et al. 2006; Lessard et al. 1999, 2001; Whyte et al. 2006).

Drugs metabolized by CYP3A4, such as alprazolam, triazolam, sertraline, mirtazapine, and nefazodone, appear to be cleared less well in elderly patients (Barbhaiya et al. 1996; Greenblatt et al. 1991; Ronfeld et al. 1997; Timmer et al. 1996). However, this may be because metabolism of CYP3A4 drugs is typically perfusion limited (i.e., dependent on hepatic blood flow, which is known to decline substantially with age) (Wynne et al. 1990). CYP3A4 makes up 30% of total hepatic CYP and nearly all of drug-metabolizing enzyme in the small bowel, and therefore is substantially responsible for "first-pass" or presystemic drug disposition (Shimada et al. 1994). Minimally, 50% of clinically used medications are at least partly dependent on CYP3A4 for their clearance. Serious toxicity has occurred when the 3A4-mediated clearance of terfenadine, astemizole, cisapride, cerivastatin, midazolam, and triazolam was inhibited (Dresser et al. 2000). CYP3A4 activity may be inhibited by grapefruit juice, protease inhibitors, macrolide antibiotics, and triazole antifungals. Among antidepressants, nefazodone and fluvoxamine are the most potent inhibitors of CYP3A4, followed by fluoxetine, through its demethylated metabolite. The very long half-life of norfluoxetine may result in interactions occurring many weeks after the initiation of fluoxetine treatment. The 3A4 enzyme is also potently induced by other drugs, such as carbamazepine, phenytoin, topiramate, modafinil, barbiturates, steroids, and St. John's wort. CYP3A4 induction will increase the likelihood of therapeutic failure for concurrently prescribed 3A4 substrate drugs. Many CYP3A4 inhibitors (e.g., diltiazem) and inducers (e.g., St. John's wort) also have been found to inhibit or induce the P-glycoprotein drug transporter, amplifying their effects on 3A4 (Yu 1999).

CYP1A2 metabolizes clozapine, olanzapine, fluvoxamine, and theophylline and contributes to the demethylation of some tertiary TCAs. This enzyme is induced by cigarette smoking, cruciferous vegetables, and charcoaled meats as well as by medications such as omeprazole and phenobarbital. Estrogen replacement therapy in postmenopausal women has been found to inhibit CYP1A2 metabolism (Pollock et al. 1999). CYP2C9 metabolizes several drugs with a narrow therapeutic index (i.e., phenytoin, tolbutamide, ibuprofen, and warfarin). It is therefore important to recognize that this enzyme may be inhibited by fluvoxamine and fluoxetine. CYP2B6 has been found to metabolize bupropion, and in vitro evidence indicates that fluoxetine, paroxetine, and sertraline may cause inhibition (Hesse et al. 2000).

Excretion

The well-established age-associated decline in renal clearance may affect excretion of psychotropic drug metabolites and lithium in older patients. The magnitude of this decline varies greatly among the aged (Pollock et al. 1992b), being exacerbated by concomitant conditions (e.g., diabetes and hypertension) and medications (e.g., nonsteroidal anti-inflammatory drugs). Accumulation of active TCA metabolites in the elderly was previously a subject of concern (Pollock et al. 1992a). Higher concentrations of bupropion and venlafaxine metabolites also have been observed in older patients and those with renal impairment, with uncertain clinical consequences (Sweet et al. 1995; Whyte et al. 2006).

PHARMACODYNAMICS OF PSYCHOTROPIC MEDICATIONS IN THE ELDERLY

Interindividual differences in pharmacodynamics become evident when those with similar plasma drug concentrations experience different effects. In general, older patients are more sensitive to adverse effects of psychotropics at lower concentrations (Pollock 1999). Homeostatic mechanisms, such as postural control, water balance, orthostatic circulatory responses, and thermoregulation, are frequently less robust in the aged. This factor may interfere with the ability to physiologically adapt to medication. For example, all psychotropics, including selective serotonin reuptake inhibitors (SSRIs), may increase the risk of falls and hip fractures (Liu et al. 1998). Similarly, the syndrome of inappropriate antidiuretic hormone secretion has been reported as an age-associated adverse effect of all SSRIs and of venlafaxine (see Kirby and Ames 2001).

Reductions in dopamine or acetylcholine function with age may increase sensitivity to antipsychotics and SSRIs (which indirectly reduce dopamine outflow) as well as medications with antimuscarinic effects. Even low serum anticholinergic levels may be associated with cognitive impairment in depressed and nondepressed elderly persons (Mulsant et al. 2002; Nebes et al. 2005). Unfortunately, anticholinergic drugs continue to be widely prescribed in older patients, including those with cognitive impairment (Roe et al. 2002).

Anticoagulant–antidepressant interactions may be both pharmacokinetic and pharmacodynamic. Fluvoxamine and fluoxetine pose the greatest risk of pharmacokinetic interactions through CYP2C9 inhibition, reducing the clearance of warfarin's active *S*-enantiomer. However, increased bleeding times with SSRIs alone or in combination with anticoagulants also may be possible as a result of depleting platelets of serotonin and attenuating their aggregation (Pollock et al. 2000b).

At present, evidence is limited that genetic differences may influence pharmacodynamics in older patients. Depressed elderly patients with the long–long (LL) serotonin transporter promoter genotype were found to have a more rapid initial response to paroxetine (Pollock et al. 2000a). This is consistent with results obtained with other SSRIs in younger patients (Serretti et al. 2006). Another study in geriatric major depression found that carriers of the short (S) allele experienced more severe adverse events during paroxetine treatment (Murphy et al. 2004). Interestingly, findings in Koreans with late-life depression were in the opposite direction—that is, better responses among carriers of the S allele (Kim et al. 2006).

Serotonin transporter polymorphisms also may influence the probability that those with dementia will manifest aggressive or psychotic disturbances (Sweet et al. 2001). Similarly, the serotonin 5-HT_{2A} receptor C102/C102 genotype was found significantly more frequently in Alzheimer's disease patients with psychosis (Nacmias et al. 2001). These intriguing reports reinforce the possibility that serotonergic dysfunction plays a prominent role in the psychiatric symptoms of dementia (Pollock et al. 2002, 2007). Given the extensive use of risperidone in the treatment of late-life psychoses and its potent affinity for the 5-HT_{2A} receptor, it is also of interest that the C102/C102 genotype was found to be associated with a more robust risperidone response in younger patients with acutely exacerbated schizophrenia than in younger patients without this genotype (Lane et al. 2002). This same variation in the 5-HT_{2A} receptor was associated with more side effects and more study discontinuations in geriatric patients treated with paroxetine but not mirtazapine (Murphy et al. 2003). Although findings from these early association studies are tenuous, it is encouraging that attempts are now being made to parse medication response by genotype in older subjects.

ANTIDEPRESSANTS IN THE ELDERLY

Treatment of Late-Life Depression

The combined prevalence of major depressive disorder and dysthymia in late life is 5%–12% in epidemiological studies; this rate is similar to the rate in the younger adult population. However, the symptom pattern and frequency of specific depressive subtypes appear to be different; older patients

have more somatic symptoms, and both the melancholic and the delusional subtypes of depression increase in frequency in older populations. In addition, some degree of cognitive impairment, whether manifest only concurrently with the depressive episode or as a function of age, is common.

As in younger patients, untreated depression in late life causes significant social, vocational, and interpersonal morbidity, and depression in late life is associated with a significant risk of mortality. Comorbid depression adversely affects the course of several disease processes; this has been best documented for ischemic heart disease. Patients with unstable angina, post–myocardial infarction, or congestive heart failure who are depressed have a higher cardiac mortality rate than do medically comparable patients who are not depressed (Musselman et al. 1998). Furthermore, the suicide rate in men (in the United States, specifically white men) increases dramatically after age 60 years and continues to rise significantly as a function of age.

Depression in late life probably represents a heterogeneous group of disorders with distinct etiologies; for example, late-onset depression, defined as having a first episode after age 60 years, is associated with brain imaging findings consistent with significant vascular disease (Figiel et al. 1991), and late-life dysthymia in men is associated with low testosterone levels (Seidman and Roose 2000). Thus, late-life depression is not simply an episode of major depression in a patient 70 years old rather than a patient 40 years old.

Studies of Antidepressant Treatment in Older Patients

The pharmacological treatment of late-life depression has long been influenced by three widely held clinical beliefs about older patients: 1) they do not respond at the same rate or as robustly as younger patients; 2) they take longer to respond to antidepressant medication, and therefore a 12-week trial is mandatory; and 3) they experience a higher rate of side effects and adverse events. Until recently, there has been a relative paucity of rigorous randomized, controlled trials of antidepressant treatment in late-life depression; consequently, these clinical beliefs have gone untested. However, perhaps stimulated by the prevalence and clinical significance of late-life depression and the need to establish safe and effective treatments, there has been a recent increase in the number of studies of antidepressant treatment for late-life depression (although most are sponsored by the pharmaceutical industry). In addition, analyses of extant data address the issue of optimal duration of treatment.

Considering the physiological changes associated with aging and the differences in the phenomenology and possible etiology of depression in late life compared with earlier in life, it is expected that clinical trials of antidepressants in late life will have a unique set of patient moderators and study design mediators that may significantly affect results. Variability in results of randomized, controlled trials of antidepressants in late-life depression may result from heterogeneity in the patient population. Treatment moderators that have been identified as significant for late-life depression include

- Subtype (e.g., melancholic or atypical)
- Severity
- Medical burden
- Social support
- Abnormalities on magnetic resonance scans indicating vascular disease
- Pattern of neurocognitive abnormalities labeled "executive dysfunction"

With respect to mediators of treatment response, the standard considerations in study design—namely, randomization, placebo versus comparator control, dosage, duration, and criteria for response and remission—are all important, but specifically the value of placebo-controlled trials versus comparator trials and optimal duration of treatment have been systematically reexamined. Sneed et al. (2008) conducted a meta-analysis of all studies published in peer-reviewed journals from 1985 to 2006 that were randomized, placebo-controlled or comparator (a comparison of two active

conditions) trials of antidepressants for the treatment of late-life depression. The intent of the meta-analysis was to determine whether rates of response to medications in comparator trials are significantly higher than rates of response to comparable medications in placebo-controlled trials—that is, whether study design significantly affects treatment outcome. Sixteen studies (9 comparator trials and 7 placebo-controlled trials) met the rigorous inclusion criteria for the meta-analysis. As hypothesized, antidepressant response rates were significantly higher in the comparator trials compared to placebo-controlled trials; the estimated probability of antidepressant response in a placebo-controlled trial was 46% as compared with 60% in a comparator trial. One possible explanation for the higher response rate to the same medication in a comparator trial is that patient, doctor, and even research rater expectations of response are higher when it is known that the subject is receiving an active medication. Irrespective of the reason that response rates are higher in comparator trials, the results of the study suggest that when clinicians want to make evidence-based treatment decisions and communicate likelihood of response to patients, data from comparator trials may be more appropriate than results of placebo-controlled trials, since comparator trials more closely approximate the clinical situation in that both patient and doctor know that an active medication is being prescribed.

Although it would be optimal if the numerous randomized, controlled trials of antidepressant treatment in late-life depression all had comparable patients, the same rigorous study design, and similar data analysis, few (if any) studies are without problems. Thus, the review of specific antidepressants that follows does not attempt to be inclusive of all studies but rather aims to illustrate the effect of medication by reviewing data from the best studies available.

Tricyclic Antidepressants

There are scores of randomized, placebo-controlled or comparator (usually an SSRI) trials of TCA treatment for late-life depression. The problem is that most of the placebo-controlled trials involving TCAs were done before the use of plasma-level measurements to ensure optimal TCA treatment. Later randomized, controlled trials that compared TCAs with SSRIs were invariably supported by the pharmaceutical industry, which had no desire to compare their new compound against optimal TCA treatment. Consequently, the preponderance of studies of TCA treatment in late-life depression reported on inadequate doses of the tertiary-amine tricyclics amitriptyline and imipramine. Nonetheless, the results of these studies established that TCAs are an effective treatment for depression in geriatric patients.

Nortriptyline

Of the tricyclics, nortriptyline has been found to induce the least orthostatic hypotension and has a documented "therapeutic window" that permits optimal dosing (Roose et al. 1981). Consequently, nortriptyline has emerged as the choice of this class of medications issued to treat late-life depression. However, there are no rigorous placebo-controlled trials of nortriptyline in late-life depression; thus, the relative effectiveness of this medication is inferred from two open trials and three randomized comparator trials.

In a study reported by Flint and Rifat (1996), 101 patients meeting DSM-III-R (American Psychiatric Association 1987) criteria for major depressive disorder were treated openly with nortriptyline. The dosing schedule was as follows: all patients achieved a dose of 75 mg by the end of week 1, and then the dose was adjusted if necessary to achieve a plasma level within the therapeutic window of 50–150 ng/mL. The treatment duration was 6 weeks, and the remission criterion was a final Hamilton Rating Scale for Depression (Ham-D; 17-item) score of 10 or less; 60% of the intent-to-treat sample and 75% of the completers met the remission criteria. To establish speed of response, the authors determined the week of treatment that the 61 patients who met criteria for remission at the end of the study first achieved sustained remission. Not surprisingly, at the end of week 1, no patient met the criteria for

remission, and thus the cumulative response rate was 0%. At week 2, 11% of the sample met the remission criteria, and at week 3, 33% met the remission criteria (thus, the cumulative rate at the end of week 3 was 11% + 33%, or 44%). At weeks 4 and 5, 25% and 20%, respectively, met the remission criteria. Thus, the accumulated remission rate at the end of week 5 was 89%. Although it is widely believed that late-life depression patients should have longer treatment trials, specifically 12 weeks, this study found that 89% of the patients who eventually recovered did so by the end of week 5. With respect to tricyclics, it may be that the slower dose escalation often used for older patients, rather than an intrinsic difference in the rapidity of response between young and old, is the critical factor accounting for delayed response.

A second open study of a therapeutic plasma level of nortriptyline reported on 42 inpatients (mean age = 70 years) with cardiac disease and melancholic depression who also were treated for 6 weeks (Roose et al. 1994). The remission criterion was a final Ham-D (21-item) score of 8 or less; the intent-to-treat remission rate was 67%, the completer remission rate was 82%, and the dropout rate was 19%.

Three randomized, controlled trials compared nortriptyline with an SSRI; two studies compared a therapeutic plasma level of nortriptyline with paroxetine, and one study compared flexible-dose nortriptyline with sertraline. Mulsant et al. (2001a) compared nortriptyline with paroxetine in 116 inpatients and outpatients (mean age = 72 years) in a 12-week trial. Patients were considered to be in remission if the final Ham-D (17-item) score was 10 or less; the intent-to-treat remission rate was 57% for the nortriptyline group and 55% for the paroxetine group. The rate of dropout due to side effects in the nortriptyline group was significantly higher than that in the paroxetine group (33% vs. 16%; $P = 0.04$).

A second randomized, controlled trial comparing nortriptyline (targeted to a therapeutic plasma level) with paroxetine is included in this chapter, although technically it should not be considered a geriatric study because the mean age of the patients was 58 years (Nelson et al. 1999). However, it is the only other study comparing a therapeutic plasma level of a tricyclic with an SSRI, and the results are consistent with those of the Mulsant et al. (2001a) study. In this trial, 81 outpatients with ischemic heart disease were treated with medication for 6 weeks. The remission criterion was a final Ham-D (17-item) score of 8 or less; in the intent-to-treat analysis, 63% of the nortriptyline group and 61% of the paroxetine group were remitters. The dropout rate for nortriptyline (35%) was significantly higher than the dropout rate for paroxetine (10%) ($P < 0.05$). The rate of remission in study completers was 85% for nortriptyline and 68% for paroxetine, which was not a statistically significant difference, although the power of this comparison was limited by the small size of the completer group.

The randomized, controlled trial comparing sertraline with nortriptyline included 210 patients (mean age = 68 years) randomly assigned to 12 weeks of medication treatment (Bondareff et al. 2000). This study did not report remission rates but only response rates, defined as a 50% reduction in Ham-D (24-item) score from baseline. The response rates for nortriptyline and sertraline were 41% and 52%, respectively.

Tricyclic side effects and safety

Unfortunately, despite their robust effectiveness, the clinical utility of TCAs in the late-life population is limited by their side-effect and safety profiles. Tricyclics have significant anticholinergic effects, and although the total anticholinergic load is lower for desipramine and nortriptyline compared with the tertiary tricyclics, even in these medications, it is still considerable. The anticholinergic effects of tricyclics result in dry mouth, constipation, and blurred vision, and more important, the geriatric population is particularly susceptible to anticholinergic-induced urinary retention and confusional states.

The major safety problem with respect to the tricyclics is cardiovascular effects (Glassman et al.

1993). Tricyclics are lethal in overdose, and as little as three times the daily dose can result in death from heart block or arrhythmias. The TCAs have type 1A antiarrhythmic activity similar to that of morizicine and quinidine and consequently are presumed to confer an increased risk of sudden cardiovascular death if given to patients with ischemic heart disease. Given the prevalence of occult and manifest ischemic heart disease in both men and women older than 60 years, the use of tricyclics in this population must reflect a careful consideration of the risk–benefit ratio.

Selective Serotonin Reuptake Inhibitors

As in younger depressed patients, the SSRIs are the most prescribed class of antidepressants for late-life depression. However, strikingly few rigorous placebo or comparator randomized, controlled trials have reported response and remission data. Within this class, the various SSRIs appear to have equivalent efficacy and side-effect profiles. There are differences in pharmacokinetics and potential for drug–drug interactions, which are of importance in the geriatric population and have been discussed earlier in this chapter.

Fluoxetine

Four large studies of fluoxetine in late-life depression have been done: 1) placebo-controlled study; 2) three-cell study comparing venlafaxine, placebo, and fluoxetine; 3) randomized, controlled trial with a comparator drug; and 4) open treatment. In the first study, fluoxetine was compared with placebo in 671 patients (Tollefson et al. 1995). The dosing schedule was fluoxetine 20 mg/day for 6 weeks, and the remission criterion was a Ham-D (17-item) score of 7 or less after 4 weeks. The intent-to-treat analysis remission rate was 23% for fluoxetine and 13% for placebo; in the completer analysis, the remission rate was 27% for fluoxetine and 16% for placebo. Although fluoxetine was significantly more effective than placebo in both the intent-to-treat and the completer analyses, this was the first large SSRI trial in a geriatric population, and in comparison to the clinical experience with therapeutic plasma levels of tricyclics, the remission rates in this study were disappointingly low.

In the comparator randomized clinical trial, patients were randomly assigned to either fluoxetine 20–40 mg or sertraline 50–100 mg for 12 weeks (Newhouse et al. 2000). The sample of 225 patients (mean age = 68 years) was somewhat unusual because the mean duration of the current episode of major depression was 9 years. The intent-to-treat remission rate was 46% for fluoxetine and 45% for sertraline, the completer remission rate was 60% for fluoxetine and 59% for sertraline, and the dropout rate was 33% for fluoxetine and 32% for sertraline. This study also reported an intriguing analysis of the response pattern of a subsample of 75 patients (42 treated with sertraline, 33 treated with fluoxetine) with a mean age of 75 years. For both sertraline and fluoxetine, 95% of the patients who achieved a 50% reduction in baseline Ham-D score did so by the end of week 8. As with the Flint and Rifat (1996) study of a therapeutic plasma level of nortriptyline, these data challenge the clinical wisdom that antidepressant trials in late-life depression must be extended to 12 weeks.

Finally, 308 patients meeting DSM-III (American Psychiatric Association 1980) criteria for major depressive disorder (mean age = 66 years) were treated openly with 20 mg of fluoxetine for 8 weeks (Mesters et al. 1992). The remission criterion was a final Ham-D (24-item) score of 10 or less; the intent-to-treat remission rate was 35%, the completer remission rate was 50%, and the dropout rate was 29%.

Sertraline

In addition to the two randomized, controlled comparator trials previously described, nortriptyline versus sertraline and fluoxetine versus sertraline, a large rigorous placebo-controlled trial of sertraline in late-life depression was recently completed (Schneider et al. 2003). In this study, 716 patients (mean age = 70 years) were randomly assigned to flexible-dose sertraline 50–100 mg or placebo in an 8-week clinical trial. The criterion for remission was a final Ham-D (17-item) score of 10

or less; the intent-to-treat remission rate was 29% in the sertraline group, compared with 23% in the placebo group ($P < 0.05$).

Paroxetine

In addition to the two previously described trials that compared nortriptyline at a therapeutic plasma level with paroxetine and in which the intent-to-treat remission rates (final 17-item Ham-D score ≤10) were 55% and 61%, respectively, a third recently completed trial compared mirtazapine with paroxetine (Schatzberg et al. 2002). In this study, 255 patients (mean age = 72 years) were randomly assigned to mirtazapine 30–45 mg or paroxetine 30–40 mg in an 8-week clinical trial. The criterion for remission was a final Ham-D (17-item) score of 7 or less; the intent-to-treat remission rates were 38% for mirtazapine and 28% for paroxetine and were not statistically different.

Citalopram and Escitalopram

Many of the studies of citalopram in a geriatric population included patients with depression and dementia or significant cognitive impairment; therefore, the results of these studies are not comparable to those of other antidepressant trials in late-life depression (Gottfries 1996). However, two studies do provide information on citalopram in this population; the first is a single-blind comparison between citalopram and a therapeutic plasma level of nortriptyline, and the second is a recently completed comparison of citalopram with placebo in depressed patients older than 75 years.

In the first study, 58 patients (mean age = 71 years) were randomly assigned to treatment with 30–40 mg of citalopram or a therapeutic plasma level of nortriptyline in a 12-week clinical trial (Navarro et al. 2001). The criterion for remission was a final Ham-D (17-item) score of 7 or less; the intent-to-treat remission rates were 69% for citalopram and 93% for nortriptyline. The remission rates for both medications were strikingly high in comparison to those in other trials; whether this results from differences in patient population or study design is not obviously apparent.

The second trial is unique in the literature because it is the only study to focus on treatment of depression in the "old-old." In this study, 174 patients were randomly assigned to treatment with either citalopram 20–40 mg or placebo in an 8-week clinical trial (Roose et al. 2002). The population was 58% female, with a mean age of 80 years and a mean baseline Ham-D (24-item) score of 24. The intent-to-treat response rate (50% reduction from baseline Ham-D score) was 41% in the citalopram group and 39% in the placebo group. The sample was divided for secondary analyses into patients with "severe" and "not severe" depression, which were defined as being either above or below the mean Ham-D score, respectively. The "not severe" group had a baseline Ham-D score of 22 and included 47 patients randomly assigned to citalopram and 59 patients randomly assigned to placebo. The criterion for remission was a final Ham-D score of 10 or less. In this group, the intent-to-treat remission rate was 34% for citalopram and 41% for placebo. The "severe" patient group had a mean baseline Ham-D score of 28 and included 37 patients randomly assigned to citalopram and 31 patients randomly assigned to placebo. In this group, the intent-to-treat remission rate was 36% for citalopram and 19% for placebo ($P < 0.05$). Thus, citalopram is significantly more effective than placebo in the "severe" patient population, but this difference resulted not from an increased efficacy of citalopram compared with "not severe" patients but from a decreased efficacy of placebo.

A third recent study—an 8-week randomized, controlled trial—compared citalopram (flexible dose 10–20 mg/day) and venlafaxine (flexible dose 75–150 mg/day) in the treatment of late-life depression (Allard et al. 2004). The study included 151 patients (mean age = 73 years; 73% female) with a baseline Montgomery-Åsberg Depression Rating Scale (MADRS) score of 27 ± 4. The response rates for venlafaxine versus citalopram were 75% and 73%, respectively, and the remission rates were 19% and 23%, respectively. The differences between the response rates and the remission rates are quite striking; it is unusual to see such a differential.

There is one randomized, controlled trial of escitalopram in the treatment of late-life depression (Kasper et al. 2005). In this study, 517 patients (mean age = 75 years; 75% female; mean baseline MADRS score = 28 ± 4) were randomly assigned to escitalopram (10 mg/day), fluoxetine (20 mg/day), or placebo. There was no significant difference in response rates across the three treatment conditions (response rates: escitalopram 46%, fluoxetine 37%, and placebo 47%).

SSRI side effects and safety

As a group of medications, the SSRIs have the same side-effect profile in older patients as in younger patients: specifically, gastrointestinal distress, agitation, insomnia, and sexual dysfunction. Discontinuation rates for SSRIs are not statistically different from the discontinuation rates reported for a therapeutic plasma level of nortriptyline in the geriatric samples.

With respect to safety, the SSRIs offer a significant advantage over the tricyclics. SSRIs are relatively benign in overdose (Barbey and Roose 1998) and have been extensively tested in patients with ischemic heart disease, in patients with congestive heart failure, and immediately post–myocardial infarction (Glassman et al. 2002; Roose et al. 1998). In contrast to the tricyclics, the SSRIs have a relatively benign cardiovascular profile and specifically do not have an effect on blood pressure, heart rate, cardiac conduction, or cardiac arrhythmias and have no indication that they carry significant cardiac risk. In a randomized, controlled trial of depressed patients post–myocardial infarction who received sertraline or placebo, the patients treated with sertraline had significantly fewer major cardiovascular events than did the patients receiving placebo. The beneficial effect of medication in this study may not exclusively or even in part result from the effective treatment of depression. SSRIs have been established to have significant "antiplatelet" effects and therefore have anticoagulant benefit above and beyond that of aspirin in patients with significant vascular disease (Musselman et al. 1998).

Other Antidepressants

Venlafaxine

One study reported meaningful information about venlafaxine in a geriatric population (Schatzberg and Cantillon 2000). In this 8-week randomized, controlled clinical trial, 204 patients (mean age = 71 years) were randomly assigned to treatment with venlafaxine 75–225 mg/day, fluoxetine 20–60 mg/day, or placebo. Remission was defined as a Ham-D (24-item) score less than 8; the intent-to-treat remission rate was 42% for venlafaxine, 29% for fluoxetine, and 38% for placebo (no statistically significant differences). Significantly more patients treated with venlafaxine (27%) and fluoxetine (19%) discontinued study participation because of side effects than did those given placebo (9%) ($P < 0.05$). Cardiovascular measures, including heart rate and measures of cardiac conduction (including pulse rate, QRS, and QTc intervals), were assessed, and neither medication induced a significant change compared with placebo in any of these measures.

Duloxetine

There is one randomized, controlled trial of duloxetine for the treatment of late-life depression. In this study 311 patients (mean baseline Ham-D score = 22 ± 4) were randomly assigned in a 2-to-1 allocation favoring duloxetine (Raskin et al. 2007). The response and remission (final Ham-D score = ≤ 7) rates were significantly greater for duloxetine than for placebo (response rates: duloxetine 37%, placebo 27% [$P < 0.001$]; remission rates: duloxetine 19%, placebo 15% [$P = 0.002$]). However, as with many other trials of antidepressant medication for the treatment of late-life depression, the remission rates are distressingly low.

Mirtazapine

As previously discussed, in one randomized, controlled comparator trial of mirtazapine versus

paroxetine in a geriatric population, the intent-to-treat remission rates were 38% for the mirtazapine group and 28% for the paroxetine-treated patients (Schatzberg et al. 2002). In this study, the rate of discontinuation due to adverse events was similar in both groups: 33% for mirtazapine and 29% for paroxetine.

Bupropion

One randomized, controlled comparator trial of bupropion versus paroxetine in late-life depression has been published, and this represents the only data available on bupropion in this population (Weihs et al. 2000). In this 6-week clinical trial, 100 patients (mean age = 70 years), with a baseline Ham-D (24-item) score of 27, were randomly assigned to treatment with either bupropion 100–300 mg/day or paroxetine 10–40 mg/day. Rates of response (defined as a 50% reduction from baseline Ham-D score) in the intent-to-treat analysis were 71% in the bupropion group and 77% in the paroxetine group. Remission data were not reported. Discontinuation rates were 17% in the bupropion group and 15% in the paroxetine group.

Duration of Antidepressant Treatment

A long-standing adage is that older patients take longer to respond to antidepressant treatment than do younger patients as a result of either the physiological effects of aging or the more treatment-resistant nature of mood disorders over time. Also, a longer time to response in the elderly may result from slower dose escalation. It is commonly believed that a lower starting dose and slower dose escalation of antidepressant medication will improve tolerability among geriatric patients. However, the "start low and go slow" paradigm evolved in the era when TCAs were the primary treatment for depression and the tertiary tricyclics amitriptyline and imipramine were more widely used than nortriptyline. In fact, the evidence does not support the view that side effects such as orthostatic hypotension or anticholinergic phenomena are minimized by slow dose escalation of the TCAs. Furthermore, the utility of the "start low and go slow" strategy for treatment with SSRIs or other antidepressants is essentially untested.

The belief that patients with late-life depression take longer to respond than younger patients has led to the dictum that for the elderly the minimum duration necessary for an adequate antidepressant trial is 12 weeks. Do all patients require a 12-week trial before they can be considered nonresponders? An affirmative answer implies that patients who are still quite ill at week 11 may improve dramatically and meet remission criteria by week 12.

Data on this issue are sparse and somewhat contradictory. Georgotas et al. (1989) reported that extending a nortriptyline trial from 7 to 9 weeks resulted in a significantly higher response rate. In this study, at the end of 7 weeks, 54% (26 of 48) of the nortriptyline-treated patients had responded, and 4 additional patients responded during the 2-week extension, bringing the total response rate to 63%. The number of slow responders to nortriptyline was small, and the slow responders had low plasma levels of nortriptyline in the early weeks of the trial and required a dosage increment. Despite these caveats, this study is frequently cited as yielding findings supporting the need for longer treatment trials in late-life depression.

Other studies suggest that speed of response to TCAs is not slowed in older patients. Studies of depressed patients older than 60 years receiving a therapeutic plasma level of TCA (either imipramine, nortriptyline, or desipramine) reached by week 2 of treatment reported that 90% of the patients who met response criteria did so by the end of week 4 (Roose 1990).

In contrast to the studies of tricyclic treatment, two 12-week randomized, controlled trials of SSRIs in late-life depression comparing sertraline with fluoxetine and sertraline with nortriptyline both reported an increase in response rates at week 12 compared with week 8 (Bondareff et al. 2000; Newhouse et al. 2000). Hypothetically, the increased number of patients meeting the response criteria

at 12 weeks represents two different groups: 1) patients who were close to meeting the response criteria by week 8 and crossed the threshold by week 12, and 2) patients who had no significant symptom reduction by week 8 but then improved dramatically over the next 4 weeks to meet the response criteria at week 12 (so-called late responders). If the significantly higher response rate at week 12 is due to patients who experienced most of their improvement between weeks 8 and 12, this would imply that all patients deserve a 12-week trial, even those who have no significant improvement by week 8. However, if the responders at week 12 already had shown significant improvement by week 8, this would imply that the additional weeks of treatment benefit only those who are well on their way to remission.

Recently, new data analyses of 12-week antidepressant treatment trials in late-life depression focused on time to response and the early identification of nonresponders (Sackeim and Roose 2002). Data for these analyses came from two industry-sponsored trials, one comparing sertraline with fluoxetine and the other, fluoxetine with nortriptyline.

In the first study, 236 patients were randomly assigned to treatment with either fluoxetine (20–40 mg/day) or sertraline (50–100 mg/day) for 12 weeks. In the second study, 210 patients were randomly assigned to treatment with either sertraline (50–150 mg/day) or nortriptyline (50–100 mg/day), also for 12 weeks. The patients who completed the 12-week trials did not differ in demographic or clinical features, nor did the groups differ in rates of response or remission. Therefore, those who completed the trial in the four groups were combined for the purpose of enhancing sample size with respect to other analyses.

For the total sample of completers (N = 304), the response rate was 69%. When the criterion for remission was a final Ham-D (24-item) score of 10 or less, the remission rate was 59%; for a final Ham-D score of 6 or less, the remission rate was 34%. The median time to onset of sustained remission was 4 weeks if remission was defined as a final Ham-D score of 10 or less, but 36% of the patients required 8 or more weeks to reach this point. If the remission criterion was a final Ham-D score of 6 or less, then the time to sustained remission was 8 weeks, with 29% reaching the criterion only in week 12. Thus, not surprisingly, time to remission is dependent on the remission criteria. However, given a remission criterion of a final Ham-D score of 10 or less, which is often used in late-life depression trials, the median time to onset of remission (4 weeks) is not prolonged compared with reports on younger depressed patients. Neither the overall response or remission rates nor the time to achieve sustained remission supports the belief that patients with late-life depression are less responsive to antidepressant medication or take longer to respond.

With respect to the early identification of nonresponders, when a remission criterion of a final Ham-D score of 6 or less is used, if a patient does not have at least a 30% improvement in the Ham-D score by week 2, he or she has only a 22% probability of being in remission at week 12, and this probability progressively decreases, so that by week 6, if a patient does not have a 30% reduction in baseline Ham-D score, the probability of remission at the end of week 12 is only 7%. As would be expected, if the remission criterion is a final Ham-D score of 10 or less, there was still strong predictive power, but it was somewhat delayed (i.e., by week 6, if a patient did not achieve a 30% reduction from baseline Ham-D score, then there was a 22% chance of being in remission at the end of the study, and this decreased to 19% by week 8). The results suggest that if there is not a moderate degree of symptomatic improvement early in treatment, clinicians can have a high level of accuracy in predicting that the patient will not adequately respond to this treatment within 12 weeks.

The most important clinical implication of these data is that clinicians no longer have to mandate a 12-week trial of antidepressant medication to all depressed patients older than 60 years. Rather, they can make informed decisions about changing or continuing treatment at the 4- and 6-week time points based on the probability that given the patient's improvement to date, he or she will or will not meet remission criteria by week 12.

ANTIPSYCHOTICS IN THE ELDERLY

Antipsychotic medications are increasingly being used in geriatric patients, particularly in dementia (Colenda et al. 2002). In the elderly, antipsychotic use in neurodegenerative disorders exceeds antipsychotic use in schizophrenia because of the difference in disease prevalence rates. In the elderly, the population prevalence of schizophrenia remains below 1%, whereas the prevalence of dementia is approximately 2%–5% for people older than 60 years, and the prevalence increases to 15%–40% for people older than 85 years of age (Thomas et al. 2001). Psychosis and behavioral dyscontrol occur in the majority of patients with dementia during their course of illness (Devanand et al. 1997; Lyketsos et al. 2000). Consequently, use of antipsychotics is greater in elderly patients with dementia than in those with schizophrenia, even though antipsychotic medications are not U.S. Food and Drug Administration (FDA) approved for the treatment of psychosis or behavioral dyscontrol in dementia (i.e., their use represents an off-label indication).

Antipsychotics: Special Issues in the Elderly

Side Effects of Antipsychotics

Older patients are more sensitive to the side effects of antipsychotics, which can include sedation, cardiac effects (e.g., tachycardia, orthostatic hypotension), anticholinergic side effects (e.g., dry mouth, blurred vision, constipation, urinary retention), neuroleptic malignant syndrome with hyperpyrexia, autonomic instability and tachycardia, pigmentary retinopathy, weight gain and associated metabolic changes, allergic reactions, and seizures (Arana 2000). In the elderly, the risk of orthostatic hypotension leading to falls and fractures, anticholinergic side effects, and the neurological syndromes of extrapyramidal side effects (EPS) and tardive dyskinesia (TD) are particularly important.

The antipsychotics most likely to cause orthostatic hypotension are low-potency conventional (or typical) antipsychotics such as chlorpromazine and thioridazine and the atypical antipsychotics clozapine, risperidone, olanzapine, and quetiapine (Tandon 1998). Low-potency conventional antipsychotics and clozapine have the most anticholinergic effects. At comparable doses, low-potency conventional antipsychotics are less likely to cause EPS than are than high-potency conventional antipsychotics such as haloperidol, but up to 50% of patients 60–80 years of age receiving conventional antipsychotics develop either EPS or TD (Jeste et al. 1999). Saltz et al. (1991) reported an incidence of TD of 31% after 43 weeks of conventional antipsychotic treatment in a sample of elderly patients, and antipsychotic-induced TD is five to six times more prevalent in elderly than in younger patients (Jeste 2000). Besides age, other risk factors for TD include early development of EPS, cumulative use of antipsychotics, duration of antipsychotic treatment, and history of alcohol abuse and/or dependence (Lohr et al. 2002). The susceptibility of older patients to the side effects of typical antipsychotics, particularly the neurological side effects of EPS and TD, requires the use of doses lower than those commonly used in young adults. Atypical antipsychotics have a lower potential for TD compared with typical antipsychotics (Jeste 2000). Although neurological side effects are less of a concern with most atypical antipsychotics, lower doses are still needed because of the older patient's susceptibility to the other side effects of antipsychotics, including anticholinergic and cardiovascular side effects.

Mortality Risks of Antipsychotics

The use of antipsychotics is associated with an increased risk of sudden cardiac death (Ray et al. 2001). Among the antipsychotics, thioridazine appears to carry the highest risk of sudden unexplained death that is believed to be due to cardiac causes (Reilly et al. 2002). Risperidone prolongs the QTc interval but has no effect on QT dispersion (Yerrabolu et al. 2000). Prolongation of the QTc interval, which is associated with the development of torsades de pointes and sudden death, is known to occur

with several antipsychotics including the atypical antipsychotic ziprasidone, but aripiprazole, a new atypical antipsychotic, may reduce the QTc interval (Goodnick et al. 2002).

Based on a review of double-blind, placebo-controlled trials of atypical antipsychotics in patients with dementia, the FDA concluded that there was a significantly greater mortality risk (1.6–1.7 times) for patients treated with these medications compared with those treated with placebo and that all antipsychotic medications must carry a black box warning to this effect (Jeste et al. 2007). Most deaths were due to cardiac or infectious causes, which generally are the most common causes of death in patients with dementia. At this time, there is no clear explanation as to why use of atypical antipsychotics is associated with an increased mortality risk in patients with dementia. There appears to be a small increase in the risk of stroke (Brodaty et al. 2003), for which the mechanism has not been identified (Jeste et al. 2007). However, the increase in stroke risk does not by itself account for the increased mortality risk (Jeste et al. 2007).

The metabolic syndrome with glucose dysregulation is a potential side effect of all antipsychotic medications, to varying degrees. New-onset type 2 diabetes mellitus or diabetic ketoacidosis may be more common with clozapine and olanzapine compared with other antipsychotics, and blood glucose levels need to be monitored in elderly patients (Jin et al. 2004). Fasting lipid levels may rise more with olanzapine than with risperidone (Meyer 2002). Weight gain is a problematic side effect of several antipsychotics, particularly olanzapine and clozapine. There is evidence that treatment with clozapine or typical antipsychotics leads to increased leptin concentrations (Hagg et al. 2001).

Sedation is one of the most common side effects of antipsychotic medications, with low-potency antipsychotics being potent sleep inducers. In addition, low-potency antipsychotics have a greater propensity to cause anticholinergic side effects, and daytime confusion and disorientation are potential complications of antipsychotic use in the elderly.

Elderly patients are often taking a large number of medications, and drug interactions need to be considered when prescribing antipsychotics. Specifically, adding fluoxetine to risperidone raises risperidone levels (Bondolfi et al. 2002), and similar effects have been reported when fluoxetine is combined with typical antipsychotics (Solai et al. 2001).

Pharmacokinetics and Pharmacodynamics of Antipsychotics in the Elderly

Age-related decreases in gut motility and the anticholinergic effects of antipsychotics may decrease absorption rates. Antipsychotic drugs undergo biotransformation primarily in the liver, with the gastrointestinal tract, lungs, and kidneys being secondary sites. Antipsychotics have slightly longer half-lives in the elderly than in the rest of the adult population (Hicks and Davis 1980). Therefore, drugs take longer to reach therapeutic blood levels and also take longer to leave the system, thereby prolonging side effects. The concomitant use of antacids may lower antipsychotic blood levels (Fann et al. 1973).

Dopamine neurons degenerate with aging, particularly after age 70 years, and decreases in the number of cholinergic receptors occur in Alzheimer's disease (AD) (Davies and Maloney 1976; Perry et al. 1977). The decrease in the number of available dopaminergic receptors reduces the tolerance of elderly patients to antipsychotics, thereby increasing the likelihood of neurological side effects, including EPS and TD.

Blockade of dopamine$_2$ (D_2) receptors is believed to be the primary mechanism of action of antipsychotics. Atypical antipsychotics are more potent antagonists at the serotonin 5-HT_{2A} receptor compared to the D_2 receptor, resulting in fewer EPS and less TD compared with typical antipsychotics (Jeste et al. 1999).

Treatment of Behavioral Complications of Dementia

Patients with dementia often develop behavioral disturbances (e.g., agitation and aggression) or psychotic features (e.g., delusions and hallucinations). As used here, the term *behavioral complications* denotes both behavioral disturbances and psychotic features. Behavioral complications occur in most forms of dementia, lead to considerable burden for caregivers, and are common precipitants of institutionalization.

Personality changes occur early in dementia and include apathy, anhedonia, irritability, inability to pay attention, depression, and loss of emotional connection (Rubin and Kinscherf 1989). In later stages, varying degrees of agitation may occur in more than half of AD patients in outpatient clinics (Devanand et al. 1997) and nursing homes (Cohen-Mansfield et al. 1989), with aggressive behavior also becoming common (Devanand et al. 1997; Swearer et al. 1988). Other disinhibited behaviors include pacing, wandering, verbal and physical aggression, repetitive calling out and screaming, and (rarely) self-mutilating behaviors. Catastrophic reactions, including bursts of anger and even violent behavior, can occur when patients are required to perform tasks beyond their cognitive capacities (Devanand et al. 1992a). Stubbornness, or refusal to complete essential activities of daily life, can be particularly frustrating for caregivers.

Psychotic symptoms are common in dementia, with the prevalence ranging from 10% to 70% across studies. The prevalence of delusions ranges from 0% to 50% in different samples of AD patients (Devanand et al. 1997; Lyketsos et al. 2000; Reisberg et al. 1989). Isolated delusional thoughts are more common than diagnosable psychotic disorders, and paranoid delusions of theft and suspicion are the most frequent types of delusions. Systematized complex delusions and grandiose delusions are relatively rare in AD and other dementias. Delusional processes in dementia can be chronic or intermittent, a feature that distinguishes them from delusions in schizophrenia. Hallucinations, which can be visual or auditory, occur in 5%–15% of patients with dementia. In AD, a typical hallucination is the conviction that someone else is in the house (i.e., phantom boarder syndrome). Diagnostic criteria for psychosis in AD have been developed on the basis of these clinical features (Jeste and Finkel 2000).

In a series of 235 patients with mild to moderate AD who were followed prospectively for up to 5 years, approximately half of the patients who manifested paranoid delusions or hallucinations at baseline were likely to manifest the same symptom 6 months later (Devanand et al. 1997), a finding consistent with other reports (Ballard et al. 1997; Paulsen et al. 2000). However, paranoid delusions or hallucinations were evident at three out of four consecutive visits (over a period of 2 years) in only 10%–15% of patients, which raises the question, still unanswered, of how long patients need to continue taking psychotropic medications after treatment response. Psychosis and behavioral dyscontrol often coexist in AD, and treatment with antipsychotics is often prescribed for one or both sets of symptoms.

Assessment of Psychopathology in Alzheimer's Disease

In elderly patients, assessment and treatment of psychopathology should occur after reversible medical conditions (e.g., occult urinary tract infection, metabolic imbalance, iatrogenic or medication-induced symptoms) have been ruled out. Because of the intrinsic nature of AD and other dementias, most rating scales have been developed as informant-based interviews. Commonly used rating scales for measurement of neuropsychiatric symptoms of AD include the Neuropsychiatric Inventory (NPI; Cummings et al. 1994), the Neuropsychiatric Inventory—Nursing Home Version (Wood et al. 2000), the Behavioral Pathology in Alzheimer's Disease Rating Scale (BEHAVE-AD; Reisberg et al. 1987), the Consortium to Establish a Registry for Alzheimer's Disease (CERAD) Behavior Rating Scale (Tariot et al. 1995), the Cohen-Mansfield Agitation Inventory (Cohen-Mansfield et al. 1989), and the Columbia University Scale for Psychopathology in Alzheimer's Disease (CUSPAD; Devanand et al. 1992b). Currently, the NPI, which uses a quantitative time-efficient, decision-tree approach, is the most widely used scale for evaluating the effects of antipsychotic treatment in patients with dementia.

Neurobiological Mechanisms of Psychosis in Dementia

AD patients with psychosis have been found to have significantly more plaques and tangles in the medial temporal–prosubicular area and the middle frontal cortex (Zubenko et al. 1991) and four to five times higher levels of abnormal paired helical filament (PHF)–tau protein in the entorhinal and temporal cortices (Mukaetova-Ladinska et al. 1993). A decrease in serotonin in the prosubiculum of the cerebral cortex has been reported in patients with psychotic compared with nonpsychotic dementia (Lawlor et al. 1995; Zubenko et al. 1991). Decreases in acetylcholine have been correlated with increases in thought disorder (Sunderland et al. 1997). Cholinergic agents, including the acetylcholinesterase inhibitors (donepezil, rivastigmine, galantamine) that are used to treat cognitive impairment in AD, may also reduce behavioral symptoms (Bodick et al. 1997; Kaufer et al. 1996; Raskind 1999). Higher levels of norepinephrine in the substantia nigra (Zubenko et al. 1991) and higher levels of β-adrenergic receptors (Russo-Neustadt and Cotman 1997) in multiple brain regions have been reported in psychotic compared with nonpsychotic patients with AD. These data suggest an enhanced responsiveness of catecholamines that may be associated with increased psychosis in AD (Peskind et al. 1995). Homozygosity of the 1 and 2 alleles of the dopamine receptor DR3 gene (Holmes et al. 2001; Sweet et al. 1998) and homozygosity for the C102 allele of the 5-HT_{2A} receptor gene (Nacmias et al. 2001) may be associated with psychosis in AD. However, the precise pathophysiology underlying psychosis in AD is still unknown.

Psychotropic Medication Use in Dementia

Earlier studies indicated that nearly half of inpatients with dementia in Veterans Administration hospitals (Prien et al. 1975) and in other settings (Michel and Kolakowska 1981) received psychotropic medications, primarily antipsychotics and benzodiazepines (Ray et al. 1980). The neurological side effects of typical antipsychotics, particularly in dementia patients in nursing homes, led to the promulgation of the Omnibus Budget Reconciliation Act (OBRA) of 1987 (Elon and Pawlson 1992), which became effective in 1990. OBRA required identification of target symptoms, justification for the use of antipsychotics, and mandatory attempts to decrease or stop the antipsychotic medication every 3 months. Nonetheless, antipsychotic medications remain the treatment of choice for behavioral complications in dementia (Devanand et al. 1998; Katz et al. 1999; Schneider et al. 1990; Street et al. 2000), and drug utilization studies show that antipsychotics are used in 30%–50% of elderly institutionalized patients (Giron et al. 2001; Lantz et al. 1990).

Studies of Antipsychotics in Dementia

The results of an earlier meta-analysis of placebo-controlled treatment trials indicated that typical antipsychotic treatment in dementia was significantly more efficacious than placebo, with the magnitude of the advantage over placebo averaging 18% (Schneider et al. 1990). In placebo-controlled clinical trials with typical or atypical antipsychotics, response rates varied between 45% and 60% for active medication and between 20% and 45% for placebo (De Deyn et al. 1999; Devanand et al. 1998; Katz et al. 1999; Street et al. 2000), with an overall advantage for antipsychotic over placebo in the range of 18%–26% (Kindermann et al. 2002; Lanctot et al. 1998). Differences in response have been moderate on average, and clinically, a complete "cure" of the target psychotic and behavioral symptoms is uncommon.

In schizophrenia, antipsychotics are often assumed to be specific for the treatment of psychosis, and improvement in behavioral dyscontrol is believed to be secondary to improvement in psychosis. However, in patients with dementia, placebo-controlled studies consistently show comparable advantages for antipsychotics over placebo for symptoms of both psychosis and behavioral dyscontrol (Brodaty et al. 2003; De Deyn et al. 1999; Devanand et al. 1998; Katz et al. 1999; Street et al. 2000).

Typical antipsychotics

Early placebo-controlled studies of typical antipsychotics used in the management of behavioral complications of dementia showed moderate efficacy with a high placebo response rate, and considerable EPS occurred even at moderate doses (Barnes et al. 1982; Finkel et al. 1995; Petrie et al. 1982; Rada and Kellner 1976). In a double-blind, placebo-controlled, randomized comparison of standard-dose (2–3 mg/day) and low-dose (0.50–0.75 mg/day) haloperidol in 71 outpatients with AD (Devanand et al. 1998), standard-dose haloperidol was efficacious and superior to both low-dose haloperidol and placebo, as measured by scores on the Brief Psychiatric Rating Scale (BPRS) psychosis factor ($P < 0.03$ and $P < 0.05$, respectively) and psychomotor agitation ($P < 0.03$ and $P < 0.04$, respectively). EPS tended to be greater for haloperidol 2–3 mg/day than for the other two conditions, primarily because of a subgroup (20%) that developed moderate to severe EPS. Other somatic side effects, cognitive performance, and daily functioning did not differ among the three treatment conditions. Low-dose haloperidol did not differ from placebo on any measure of efficacy or side effects. The results indicated a favorable therapeutic profile for haloperidol at a dosage of 2–3 mg/day, although a subgroup did develop moderate to severe EPS (Devanand et al. 1998). In another study that compared the SSRI citalopram, the typical antipsychotic perphenazine, and placebo, citalopram was comparable to perphenazine in efficacy and significantly superior to placebo, with an advantageous side-effect profile (Pollock et al. 2002). While intriguing, replication of these findings with an SSRI antidepressant is needed before citalopram can be recommended for treatment of behavioral complications in dementia.

A multicenter study yielded findings that contradicted the earlier literature on typical antipsychotics, reporting no significant advantage for haloperidol over either trazodone or placebo in 149 patients with AD (Teri et al. 2000). However, that study had several methodological flaws, including the assignment of a subset of patients at only some of the sites to receive behavioral treatment that was not administered in a double-blind manner (Teri et al. 2000).

Atypical antipsychotics

Because of their more favorable safety profile, the atypical antipsychotics have gradually replaced typical antipsychotics in the treatment of behavioral complications in dementia. Atypical antipsychotics can be safely administered with cholinesterase inhibitors (e.g., donepezil, rivastigmine, galantamine), which are used to treat the cognitive impairment of dementia (Weiser et al. 2002). The choice of atypical antipsychotic depends on the patient's clinical profile and the medication's side-effect profile (e.g., a patient prone to falls should receive a medication that is not likely to cause orthostatic hypotension). Clozapine, risperidone, paliperidone (risperidone metabolite), olanzapine, quetiapine, aripiprazole, and ziprasidone are the atypical antipsychotics that are currently available.

Clozapine

Clozapine was the first atypical antipsychotic available in the United States. Clozapine causes substantial serotonergic blockade and has antiadrenergic and antimuscarinic properties (Lieberman 1998). Clozapine may be more efficacious than other antipsychotics in schizophrenia, and it carries essentially no risk of TD (Kane et al. 1988). Circulating levels of clozapine rise with dose and age and may be slightly higher in women than in men; sedation is common, and seizure potential is elevated (Centorrino et al. 1994; Kurz et al. 1998). Clozapine's anticholinergic properties can lead to dry mouth and constipation and can adversely affect cognition in the elderly. Also, intensive monitoring is required for blood dyscrasias, particularly agranulocytosis, which is reported to occur in 0.38% of patients (Kane et al. 1988). These factors, as well as the increased risk of falls and fractures related to the side effect of orthostatic hypotension, limit the use of clozapine in the elderly. Partly because of these safety concerns, there have been no double-blind, placebo-controlled trials using clozapine to treat behavioral complications in dementia. The few retrospective reviews and case reports available indicate moderate efficacy but with significant adverse events, suggesting very low tolerability (Chengappa et al. 1995; Oberholzer et al. 1992; Pitner et al. 1995). Therefore, clozapine is rarely used

in patients with dementia. Its use should be considered only when other antipsychotic medication treatment has failed to yield improvement.

Risperidone

Risperidone has serotonin 5-HT_2 and dopamine D_2 blocking properties, α_1- and α_2-adrenergic blocking properties, minimal histaminergic H_1 blocking properties, and little affinity for cholinergic receptors (Janssen et al. 1988). Its elimination half-life is between 20 and 22 hours, allowing for once-a-day dosing (Byerly and DeVane 1996).

In a multicenter study of young adults with schizophrenia that compared risperidone 2, 6, 12, and 16 mg/day with haloperidol 20 mg/day, risperidone 6 mg/day was efficacious and had the best therapeutic profile, with a low propensity for EPS (Chouinard et al. 1993). However, the optimal risperidone dosage range is much lower in elderly patients (Katz et al. 1999). Compared with the other atypical antipsychotics, risperidone may be more likely to lead to EPS and TD, although this risk is considerably lower than with typical antipsychotics such as haloperidol (Jeste 2000). In 255 elderly institutionalized patients with dementia and without baseline TD who were treated with risperidone at an average daily dose of 0.96 (SD = 0.53) mg, the 1-year cumulative incidence of persistent emergent TD was a relatively low 2.6% (Jeste et al. 2000). Risperidone is mildly sedating and has the potential to cause orthostatic hypotension, although the latter effect is uncommon when low doses are used in the elderly (Katz et al. 1999).

In a multicenter study, 625 nursing home patients (mean age = 83 years) with dementia (73% AD, 15% vascular, 12% mixed dementia; mean 30-item Mini-Mental State Examination [MMSE] score = 6.6) who had behavioral complications were randomly assigned to receive risperidone—at 0.5 mg/day, 1.0 mg/day, or 2.0 mg/day—or placebo for 12 weeks (Katz et al. 1999). The clinical trial was completed by 435 (70%) patients, with discontinuations primarily due to adverse events (12% of patients receiving placebo; 8%, 16%, and 24% of patients receiving 0.5, 1.0, and 2.0 mg/day of risperidone, respectively). At study endpoint, response rates for risperidone 1 mg/day (45%) and 2 mg/day (50%) were significantly superior to rates for placebo and risperidone 0.5 mg/day, which showed similar response rates (33%). Patients receiving risperidone 2 mg/day were more likely than those receiving risperidone 0.5 mg/day or 1 mg/day to develop EPS and sedation, suggesting a relatively narrow therapeutic window. Orthostatic hypotension was a relatively infrequent side effect in this study (Katz et al. 1999). Therefore, a risperidone starting dosage of 0.5 mg/day, with gradual upward dosage titration to 1–2 mg/day, is recommended. This dosage range is far lower than the optimal risperidone dosage of 6 mg/day in adults with schizophrenia (Chouinard et al. 1993). A meta-analysis of four placebo-controlled trials with risperidone found that it was superior to placebo in treating psychosis and agitation, particularly in severely disturbed patients (Katz et al. 2007). Although a long-acting injectable risperidone preparation is available, that formulation has not been studied in the treatment of behavioral complications of dementia. This issue is particularly relevant for patients who may not take oral medications on a regular basis.

Paliperidone

Paliperidone, or 9-OH risperidone, is a metabolite of risperidone that has been recently approved for the treatment of schizophrenia. Paliperidone extended-release (ER) tablets need to be taken once daily. There is a lack of information on use of paliperidone ER in patients with dementia. In a 6-week randomized, placebo-controlled, double-blind trial of paliperidone in adults diagnosed with schizophrenia, paliperidone ER 6 mg/day and 12 mg/day led to comparable improvement in positive and negative symptoms, but only the 6-mg/day dosage was associated with improvement in personal and social functioning (Marder et al. 2007). The medication showed comparable efficacy to a treatment arm with olanzapine 10 mg/day in the same study. Another study showed that paliperidone at dosages of 3–9 mg/day was superior to placebo in the treatment of schizophrenia (Davidson et al.

2007). Paliperidone ER provides a useful treatment alternative in patients whose compliance may be suboptimal. However, further studies are needed to evaluate its side-effect profile in the elderly, particularly in patients with dementia.

Olanzapine

Olanzapine blocks multiple receptor sites, including serotonin 5-$HT_{2A/2C}$ and dopamine $D_{4/3/2/1}$ (serotonin-to-dopamine receptor binding ratio of 8:1), histaminergic H_1 receptors, muscarinic acetylcholine receptors, and noradrenergic α_1 receptors (Bymaster et al. 1996). Olanzapine is well absorbed, is unaffected by food, and with a mean half-life of 30 hours, it can be used once a day (Fulton and Goa 1997).

Sedation and weight gain are prominent side effects of olanzapine, and its use has been associated with the development of metabolic syndrome. Orthostatic hypotension is also of concern because it can lead to falls and fractures, but this side effect is uncommon when low doses are used in elderly patients (Street et al. 2000). Intramuscular olanzapine is a useful alternative to intramuscular haloperidol in the treatment of acutely psychotic, agitated patients with schizophrenia (Breier et al. 2002a) and may be a useful alternative to intramuscular lorazepam in patients with dementia (Meehan et al. 2002).

In an 8-week double-blind, randomized treatment trial of 238 elderly AD outpatients with behavioral complications (mean age = 78.6 years), olanzapine at an average daily dose of 2.4 mg was not superior to placebo. The lack of efficacy, however, may have been attributable to use of suboptimal dosages (Satterlee and Sussman 1998). In a second double-blind, placebo-controlled multicenter clinical trial, 206 nursing home patients (mean age = 83 years) with AD (mean MMSE score = 6.9) and behavioral complications were randomly assigned to placebo or fixed-dose olanzapine 5 mg/day, 10 mg/day, or 15 mg/day for 6 weeks. Olanzapine 5 mg/day was significantly more efficacious than placebo, but the 10-mg/day and 15-mg/day dosages were not superior to placebo. The prominent side effects of sedation and weight gain were limiting factors at the higher dosages (Street et al. 2000). Clinically, a starting dose of 2.5 mg/day with gradual upward titration is recommended.

Quetiapine

Quetiapine acts as an antagonist at multiple neurotransmitter receptors in the brain, including dopamine D_1, D_2, serotonin 5-HT_{1A} and 5-HT_2, histamine H_1, and α_1- and α_2-adrenergic receptors. D_2 receptor affinity is less than 5-HT_2 receptor affinity. Quetiapine has no appreciable binding affinity to cholinergic muscarinic or benzodiazepine receptors (Casey 1996). Although it has a short half-life (approximately 3–6 hours; Fulton and Goa 1997), efficacy has been documented with twice-daily administration (McManus et al. 1999).

The incidence of EPS is very low. The risk of a rare lenticular and corneal opacity was reported in pre-drug-release studies (Shahzad et al. 2002). However, it remains unclear whether this potential side effect occurs in elderly patients, because the high prevalence of lenticular opacities in the normal elderly population makes it difficult to evaluate this possible side effect (Tariot et al. 2006).

In a study of 284 elderly patients with dementia, quetiapine (average dose 96.9 mg) and haloperidol (average dose 1.9 mg) were indistinguishable from placebo on most measures of efficacy, although haloperidol led to more EPS (Tariot et al. 2006). The optimal dose for quetiapine is undetermined because dose comparison studies have not been conducted in patients with dementia. Wide dose ranges from 25 to 800 mg/day are used in clinical practice. In the absence of double-blind, placebo-controlled data clearly demonstrating its superiority over placebo, quetiapine cannot be recommended as a first-line antipsychotic medication to treat behavioral complications in patients with dementia. However, physicians often do prescribe quetiapine because of its relatively benign side-effect profile. Sedation is the most common side effect with this medication.

Ziprasidone

Ziprasidone is used at dosages of 80–160 mg/day in adults (Arato et al. 2002). Unlike the other atypical antipsychotics, it causes little weight gain, produces minimal to no EPS, and has no anticholinergic side effects. However, ziprasidone can cause prolongation of the QTc interval on the electrocardiogram, and this side effect may limit its use in elderly patients with cardiovascular disease. There is a lack of published data on the use of ziprasidone in elderly patients and no controlled trials in dementia. Ziprasidone's potential to prolong the QTc interval on the electrocardiogram requires monitoring, but it causes less weight gain than most other antipsychotics (Arato et al. 2002).

Aripiprazole

A placebo-controlled study of aripiprazole in 208 outpatients with AD who had behavioral complications showed no advantage for aripiprazole on the main outcome measure (NPI score), but there was superiority on secondary outcome measures (BPRS psychosis and Core scores). The average dosage used was 10 mg/day, and it was generally well tolerated (De Deyn et al. 2005). These limited data suggest that aripiprazole can play a role as a second-line atypical antipsychotic treatment in AD patients with behavioral complications.

Comparisons among antipsychotics

Head-to-head comparison studies show few differences between typical antipsychotics in the treatment of behavioral complications in dementia (Barnes et al. 1982; Carlyle et al. 1993; Petrie et al. 1982; Smith et al. 1974; Tsuang et al. 1971). In the first comparison of a typical and an atypical antipsychotic, patients with dementia and behavioral complications were randomly assigned to receive flexible-dose risperidone, haloperidol, or placebo (De Deyn et al. 1999). In 344 patients, risperidone (average dosage = 1.1 mg/day), haloperidol (average dosage = 1.2 mg/day), and placebo showed improvement rates of 54%, 63%, and 47%, respectively, at week 12 ($P = 0.25$). Likewise, no significant differences in improvement were seen between the groups on psychosis scores. In post hoc analyses, both haloperidol and risperidone were significantly better than placebo at reducing the total BEHAVE-AD and aggression cluster scores ($P = 0.01$), and risperidone was superior to haloperidol on the aggression cluster score ($P = 0.05$). Patients taking haloperidol had significantly higher EPS scores at endpoint than did patients taking either risperidone or placebo, with no significant difference in EPS scores between patients receiving risperidone and placebo (De Deyn et al. 1999). Overall, risperidone's efficacy was comparable to that of haloperidol, with a superior side-effect profile.

Early studies reported conflicting data on whether atypical antipsychotics show superior efficacy when compared with typical antipsychotics in mixed-age samples of schizophrenic patients (Arvanitis and Miller 1997; Geddes et al. 2000; Kane et al. 1988). The Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) in adults with schizophrenia showed only marginal superiority in antipsychotic effectiveness for olanzapine compared with typical and other atypical antipsychotics (Lieberman et al. 2005). In England, the Cost Utility of the Latest Antipsychotic Drugs in Schizophrenia Study (CUtLASS) of 227 patients with schizophrenia did not show any differences in treatment response for atypical versus typical antipsychotics (Jones et al. 2006).

In dementia, comparisons of haloperidol and risperidone led to equivocal results (Chan et al. 2001; De Deyn et al. 1999; Suh et al. 2004). In the 421 elderly patients who participated in the AD component of CATIE that compared risperidone, olanzapine, quetiapine, and placebo (first randomized phase), there were no significant differences in time to discontinuation because the superior efficacy of risperidone and olanzapine was compromised by their increased propensity to side effects; quetiapine was indistinguishable from placebo (Schneider et al. 2006). These findings indicate that efficacy must be weighed against side effects when prescribing risperidone or olanzapine in a patient with dementia

and that quetiapine may not be effective.

Studies of antipsychotics versus benzodiazepines in dementia

The few studies that compared antipsychotics with benzodiazepines suffered from methodological flaws, particularly in sample selection and study design (Burgio et al. 1992; Covington 1975; Kirven and Montero 1973; Stotsky 1984; Tewfik et al. 1970). The data available from these studies do not indicate superiority for benzodiazepines over antipsychotics in the treatment of behavioral complications in patients with dementia.

Benzodiazepines are known to have deleterious effects on learning and memory in healthy subjects (Ghoneim et al. 1981; Jones et al. 1978; Liljequist et al. 1978), particularly in the elderly (Pomara et al. 1991). Benzodiazepines can lead to tolerance and dependence, and worsening of cognition is a concern. Therefore, benzodiazepines should be used in low doses and restricted to short-term crisis management of agitated and anxious behaviors if antipsychotics or other medications are ineffective.

Studies of anticonvulsants and other agents in dementia

A small-sample study suggested that carbamazepine was effective in the treatment of behavioral complications of AD (Tariot et al. 1998), and there were suggestions that valproate was efficacious in a single-site study by the same research group (Porsteinsson et al. 2001). However, valproate at an average dosage of 800 mg/day did not show superiority over placebo in a larger study of 153 nursing home patients who participated in a double-blind, placebo-controlled trial (Tariot et al. 2005). Nonetheless, anticonvulsants such as valproate are prescribed commonly in nursing homes, presumably because of their relatively benign side-effect profile. To date, no published studies have compared an antipsychotic with an anticonvulsant in the treatment of behavioral complications in patients with dementia.

Studies with other medications, such as buspirone (Lawlor et al. 1994), trazodone (Sultzer et al. 1997; Teri et al. 2000), lithium (Holton and George 1985), and propranolol (Shankle et al. 1995; Weiler et al. 1988), have involved case series or small samples, usually without placebo control. These medications can be considered as therapeutic options only after antipsychotic treatment has failed.

Choice of Antipsychotic for Treatment of Behavioral Complications of Dementia

Given the relative lack of differences in efficacy among antipsychotics (except the possible lower efficacy for quetiapine) for treating behavioral complications in dementia, the potential side-effect profile should determine the choice for individual patients (Ellingrod et al. 2002). Because of its problematic side-effect profile and its requirement for extensive blood-level monitoring, clozapine should be reserved for those patients who do not respond to the other available antipsychotics. Patients prone to orthostatic hypotension (e.g., patients receiving β-blockers) may develop this side effect while taking risperidone or olanzapine, although postural hypotension is uncommon at low doses (Katz et al. 1999; Street et al. 2000). Olanzapine causes weight gain and is strongly sedating, but the latter side effect may be advantageous in patients with prominent insomnia. The metabolic syndrome can occur with all antipsychotics but is most likely to occur with olanzapine. Quetiapine is generally well tolerated, but it can be sedating. Among the atypical antipsychotics, risperidone is the most likely to cause EPS, so olanzapine or quetiapine should be preferred in elderly patients who have parkinsonian features. The incidence of TD is much lower with atypical antipsychotics than with the typical antipsychotic haloperidol (Jeste et al. 2000). In a study of 35 agitated patients with dementia who were switched from haloperidol to risperidone, the crossover was generally safe and effective (Lane et al. 2002). Overall, the decreased likelihood of neurological side effects, both short-term and long-term, makes atypical antipsychotics the treatment of choice in these patients.

Optimal Antipsychotic Dosing Strategy

It is important to avoid using excessive antipsychotic doses in elderly patients with dementia, who are particularly prone to side effects (e.g., EPS). On the other hand, using too low a dose may reduce efficacy. As already described, several placebo-controlled studies have compared different doses of antipsychotic medications: haloperidol (Devanand et al. 1998), risperidone (Katz et al. 1999), and olanzapine (Street et al. 2000). The studies with haloperidol and risperidone produced similar results: very low doses were ineffective, whereas high doses led to side effects, suggesting a relatively narrow therapeutic window for these medications in dementia patients who develop behavioral complications. The optimal dosage for olanzapine appears to be 5 mg/day, based on the study comparing 5, 10, and 15 mg/day, although the lack of superior efficacy for the higher dosages (10–15 mg/day) is a little puzzling (Street et al. 2000). As discussed earlier, the optimal quetiapine dosage remains uncertain. To date, there is no published information available on the optimal dose of ziprasidone in this patient population.

These dose-finding and related studies have helped refine the dosing strategy for treating behavioral complications in dementia. In patients with AD, risperidone should be started at 0.25–0.50 mg/day at bedtime (or twice-daily dosing), with a 0.5-mg/day increase per week to a maximum of 2 mg/day (or possibly 3 mg/day). Olanzapine should be started at 2.5 mg/day or 5.0 mg/day at bedtime and slowly increased to a target daily dose of 5–10 mg. Quetiapine should be started at 25 mg twice daily, with dose increases as tolerated up to 300 mg twice daily, based solely on clinical response and side effects, because the optimal dosage range for quetiapine has not been identified. If a typical antipsychotic is used, a starting dose equivalent to haloperidol 0.5 mg/day is suggested, with subsequent individualized titration to achieve an optimal tradeoff between efficacy and side effects.

Use of Concomitant Psychotropics

Anticholinergic agents to treat EPS should be avoided, particularly in AD, in which the cholinergic deficit is believed to underlie much of the cognitive impairment. In some patients, the concomitant use of a hypnotic (e.g., zolpidem 5–10 mg or zaleplon 5–10 mg) may be required. Trazodone at dosages of 25–200 mg/day can also be used as a hypnotic in these patients. As noted earlier, benzodiazepine use should be limited to short-term crisis management of anxiety or agitation.

Optimal Duration of Antipsychotic Treatment in Dementia

A trial of 6–12 weeks usually is sufficient to determine the outcome of an antipsychotic treatment trial. If the optimal antipsychotic dose is reached quickly, clinical response may occur within the first 1 or 2 weeks. On the other hand, the need to adjust the dosage because of side effects may require a relatively prolonged trial period.

The expected natural course of target symptoms during the course of dementia should be considered in determining the duration of antipsychotic treatment. Delusions and hallucinations are moderately persistent, whereas agitation usually persists for several months to years during the course of AD (Devanand et al. 1997). Currently, there is conflicting evidence on how long these patients need to be continued on antipsychotic medications. One report suggested that antipsychotics and other psychotropics can be discontinued in nursing home patients with dementia without increased risk of relapse (Cohen-Mansfield et al. 1999), but other reports indicate a moderate to high rate of relapse after discontinuation (Avorn et al. 1992; Fitz and Mallya 1992; Horwitz et al. 1995). Until large-scale systematic, controlled discontinuation trials are conducted to clarify the optimal duration of treatment, a reasonable approach is to attempt gradual tapering of the antipsychotic medication after 1 year of continuous treatment.

Antipsychotic Effects on Cognition and Activities of Daily Living

One concern associated with use of antipsychotic medications in dementia is that the anticholinergic activity of antipsychotics may further compromise the already damaged central cholinergic projections

in AD. The level of cognitive impairment may be increased by the use of antipsychotics with strong anticholinergic properties or by the addition of anticholinergic agents to treat drug-induced EPS. Therefore, if EPS develops following antipsychotic treatment in a patient with dementia, switching to an antipsychotic that is less likely to cause EPS is preferable to adding an anticholinergic medication to treat the EPS. At another level, the sedation produced by antipsychotics may worsen the degree of disorientation and cognitive impairment in AD.

Antipsychotic Blood-Level Monitoring

Little work has examined the utility of monitoring antipsychotic blood levels in patients with dementia. In a study that compared haloperidol 2–3 mg/day, haloperidol 0.5–0.75 mg/day, and placebo, plasma haloperidol levels were detectable in all patients at the 2–3 mg daily dosage, and blood levels showed stronger correlations with efficacy and EPS than did oral dosages (Pelton et al. 2003). Few of the patients had ever received antipsychotics prior to entering the study, and this lack of previous exposure to antipsychotics may have precluded the alterations in drug absorption and metabolism that occur with chronic antipsychotic treatment in schizophrenia, with resultant distortion of the relationship between oral dosage and blood level. Interestingly, in this series of AD patients, therapeutic effects occurred at haloperidol blood levels that were invariably below the postulated therapeutic window of 5–15 ng/mL in schizophrenia (Van Putten et al. 1992; Volavka et al. 1992). Also, EPS developed in some patients at these low blood levels, suggesting that the increased sensitivity to antipsychotics seen in dementia is not likely to be attributable to pharmacokinetic changes. A pharmacodynamic explanation (e.g., loss of dopamine receptors leading to greater sensitivity to even low oral dosages of antipsychotic medication) is more likely. In contrast to the associations observed with the typical antipsychotic haloperidol, clinically relevant associations between blood levels of atypical antipsychotics and either efficacy or side effects have not been demonstrated (Jeste 2000).

Monitoring Treatment of Behavioral Complications in Dementia

The heterogeneous nature of behavioral complications suggests that specific target symptoms should be identified before initiating antipsychotic treatment, and these target symptoms should be monitored serially during the course of treatment. A scale like the NPI can also be used. In addition to neurological and other common antipsychotic side effects, cognition and activities of daily living need to be monitored, preferably with brief instruments such as the MMSE. In patients who are being maintained for extended periods on antipsychotics, assessment for TD using the Abnormal Involuntary Movement Scale should be conducted at regular intervals. Periodic attempts should be made to taper or discontinue the antipsychotic, although the optimal duration of continuation antipsychotic treatment remains to be established.

Antipsychotics in Other Neurodegenerative Disorders in the Elderly

The relative efficacy of antipsychotics in different subtypes of dementia (e.g., AD and vascular dementia) has not been studied extensively. The antipsychotic treatment trials that included patients with vascular, mixed, and other forms of dementia did not reveal any differences in treatment response among the diagnostic subtypes of dementia (De Deyn et al. 1999; Katz et al. 1999). With the exceptions of diffuse Lewy body disease and Parkinson's disease, the recommendations for the use of antipsychotics in AD generally apply to their use in other types of dementia.

Diffuse Lewy body disease (DLBD) is a subtype of dementia characterized by prominent EPS, fluctuating clinical course, hallucinations, and extreme sensitivity to the neurological side effects of antipsychotics (McKeith 2006). DLBD has features that overlap with those of AD and Parkinson's disease, and the boundaries of DLBD as a diagnostic entity remain controversial. Sensitivity to typical antipsychotics is one of the defining criteria for DLBD (McKeith 2006), and atypical antipsychotics may be safer to use in these patients. A post hoc analysis of the olanzapine dose comparison study in AD

suggested that olanzapine was safe and effective for the subgroup of patients who met diagnostic criteria for DLBD (Cummings et al. 2002).

Patients with Parkinson's disease can develop iatrogenic psychosis caused by the levodopa–carbidopa combination (Sinemet) or dopamine agonists. Lowering the dose of the dopaminergic agent will often lead to remission of psychotic symptoms, but the price paid may be an unacceptable increase in parkinsonian symptoms (Breier et al. 2002b). In such cases, antipsychotics with a very low propensity to cause EPS can be considered. However, in a series of five Parkinson's disease patients who developed psychosis, olanzapine was not effective in treating psychosis and was associated with worsening motor function and sedation (Marsh et al. 2001), and two double-blind, placebo-controlled trials did not find an advantage for olanzapine over placebo in these patients (Breier et al. 2002b). Clozapine may be of some value in patients with Parkinson's disease (J. H. Friedman and Fernandez 2002), but quetiapine may be the preferred antipsychotic in this disorder. Long-term quetiapine use is generally well tolerated in patients with Parkinson's disease or DLBD (Fernandez et al. 2002).

In patients with delirium, short-term antipsychotic administration is a standard treatment strategy, particularly antipsychotic medications with low anticholinergic properties, such as haloperidol (Tune 2002). Atypical antipsychotics are useful in the management of delirium, and olanzapine has been reported to be safe and efficacious for the treatment of symptoms of delirium in hospitalized patients (Breitbart et al. 2002).

Antipsychotics in Late-Life Schizophrenia

The majority of elderly schizophrenic patients were first diagnosed as young adults, but a minority of patients are first diagnosed with schizophrenia later in life. The International Late-Onset Schizophrenia Group reached a consensus that the diagnoses of late-onset schizophrenia (onset after age 40 years) and very-late-onset schizophrenia (onset after age 60 years) have face validity and clinical utility (Howard et al. 2000). Although age at onset affects the clinical presentation to some extent (Sable and Jeste 2002), it does not appreciably influence the likelihood of response to antipsychotics or the occurrence of side effects (Sable and Jeste 2002).

Studies of Antipsychotics in Elderly Patients With Schizophrenia

Most elderly schizophrenic patients with disease onset in young adulthood have been maintained on antipsychotic medications for many years, often decades, as they enter old age. Tapering and stopping antipsychotic medications in schizophrenia is associated with a high risk of relapse (Csernansky and Schuchart 2002). This risk has made it difficult to conduct placebo-controlled trials in samples of elderly schizophrenic patients (Sable and Jeste 2002). However, because many of these patients have taken typical antipsychotics for many years and have developed EPS and/or TD over time, there is often a need to switch from a typical to an atypical antipsychotic to reduce the neurological toxicity profile. In elderly schizophrenic patients, switching from typical antipsychotics to risperidone has been reported to be effective and well-tolerated (Barak et al. 2002). Atypical antipsychotics appear to be at least as efficacious as and better tolerated than typical antipsychotics in the elderly, and a study of veterans suggested that adherence to atypical antipsychotics is slightly higher than adherence to typical antipsychotics (Dolder et al. 2002).

In a 4-month comparison trial of flexible-dose risperidone (n = 175) and quetiapine (n = 553) in 728 mixed-age patients with a variety of psychotic disorders, quetiapine was as effective as risperidone and less likely to require adjustment of concomitant antiparkinsonian medication. However, quetiapine was associated with more sedation, dry mouth, and dizziness (Mullen et al. 2001). In another study of patients with treatment-refractory schizophrenia in a long-stay state hospital, olanzapine and risperidone showed comparable efficacy (Dinakar et al. 2002). Quetiapine was evaluated in a sample of 151 elderly psychotic patients (mean age = 77 years), among whom 40% had schizophrenia, bipolar disorder, or psychotic depression; 50% had psychosis associated with AD; and 10% had

psychosis associated with Parkinson's disease. The median quetiapine dosage was 100 mg/day (range = 100–400 mg/day). Significant improvement was seen in the primary outcome measure of psychosis as measured by the Brief Psychiatric Rating Scale ($P < 0.0001$) and Clinical Global Impressions ($P < 0.01$). The prominent side effects included somnolence in 32%, dizziness or postural hypotension in 13%, and EPS in 6% (McManus et al. 1999).

In 184 elderly patients (mean age = 76.1 years), 72% with AD and 28% with other psychoses (mainly schizophrenia), open-label quetiapine was administered over 52 weeks. A total of 89 patients remained on quetiapine for the entire year, with the main reasons for withdrawal being lack of efficacy (19%), adverse events or intercurrent illness (15%), and failure to return for follow-up (13%). In this sample, quetiapine at a median dosage of 137.5 mg/day was effective, with 49% of the patients showing a 20% or greater decline in BPRS scores. The main side effects were sedation (31%), dizziness (17%), and postural hypotension (15%) (Tariot et al. 2000). EPS-related adverse events occurred in 13% of the patients, but overall ratings on an EPS scale showed a small improvement from baseline, and new-onset TD did not develop in any patient over the 1-year period. Although limited by the lack of placebo control or comparison with another antipsychotic to establish efficacy, the relatively benign side-effect profile of quetiapine is noteworthy. The CATIE studies suggested that quetiapine's lack of efficacy compared with olanzapine and risperidone (quetiapine did not separate from placebo) should be an equally important consideration (Lieberman et al. 2005; Schneider et al. 2006).

Few data on the use of ziprasidone in elderly schizophrenic patients have been published, perhaps because of its increased propensity to prolong the QT interval on the electrocardiogram, which may be problematic in elderly patients.

In all age groups, it has been difficult to demonstrate that the atypical antipsychotics approved for use in the United States improve negative symptoms (e.g., anhedonia, apathy), even though this putative effect was one of the factors driving the development of these compounds. However, medications approved in Europe (e.g., amisulpride) have been shown to be efficacious in improving the negative symptoms of schizophrenia in controlled studies (Moller 2001).

Treatment and Dosing

In elderly patients with schizophrenia, a thorough evaluation followed by treatment with low doses of atypical antipsychotics is the optimal strategy. When appropriate, antipsychotic treatment may need to be combined with psychosocial intervention (Sable and Jeste 2002).

The doses of typical antipsychotics used in elderly patients with schizophrenia need to be lower than the doses used in young adults (Jeste 2000), but published dose-comparison studies of individual antipsychotics in these patients are lacking. Abrupt withdrawal of atypical antipsychotics, particularly quetiapine, has not been shown to cause major adverse effects, but nonetheless, gradual withdrawal over a few days is advisable for all antipsychotics (Cutler et al. 2002). Although atypical antipsychotics can be safely combined with cholinesterase inhibitors in schizophrenia, a study in patients receiving risperidone found no cognitive benefit from adding donepezil compared with adding placebo (J. I. Friedman et al. 2002).

Antipsychotics in Other Psychotic Disorders in the Elderly

Late-onset delusional disorder is uncommon. As is the case in young adults, this disorder is difficult to treat, and the delusions often do not remit even with adequate antipsychotic treatment. The diagnosis of paraphrenia overlaps considerably with current nomenclature for late-onset schizophrenia, and atypical antipsychotics are the treatment of choice for this disorder (Howard et al. 2000).

Psychotic depression is an uncommon but clinically important diagnosis in the elderly. Based on studies in mixed-age samples, antipsychotics combined with antidepressants are the pharmacological

treatment of choice in psychotic depression, but electroconvulsive therapy (ECT) is still considered the most effective treatment for this disorder (Mulsant et al. 2001b; Sackeim et al. 1995; Spiker et al. 1985). Expert consensus guidelines suggest that antipsychotic medication should be continued for 6 months following treatment response in psychotic depression (Alexopoulos et al. 2001), although sparse information from controlled trials is available on this issue. In a sample of 29 elderly patients with psychotic depression who responded to combination antipsychotic–antidepressant or ECT, 25% relapsed during continuation treatment (Meyers et al. 2001). No significant difference in relapse rates was found between patients receiving nortriptyline plus perphenazine and patients receiving nortriptyline alone. However, combination therapy was associated with more EPS, increased risk of TD, and falls. Although these data suggest that continuation treatment with antidepressant alone may be sufficient and perhaps optimal in geriatric psychotic depression, more data from controlled studies with typical or atypical antipsychotics are needed before this approach can be recommended for standard clinical practice.

Antipsychotics are used widely in the treatment of the manic phase of bipolar disorder across the life span (Levine et al. 2000). In bipolar disorder, there is ample evidence for the efficacy of typical and atypical antipsychotics, both individually and in combination with mood stabilizers (Sachs et al. 2002; Tohen et al. 2002). However, there is a surprising lack of data on the use of antipsychotics in geriatric patients with bipolar disorder. Lithium's toxicity, particularly in the neurological domain, is problematic in the elderly (McDonald 2000). Hence, anticonvulsants and atypical antipsychotics are used frequently to treat mania in elderly patients. However, in the absence of controlled data, the optimal choice of antipsychotic and the optimal dose to use in these patients are open questions that need to be answered in future research.

Although obsessive-compulsive disorder is not considered a psychotic illness, there is evidence that atypical antipsychotics are useful adjunctive medications in adults with this disorder (Denys et al. 2002). However, comparable data are lacking in geriatric patients.

CONCLUSION

Clearly, antipsychotic medications, particularly atypical antipsychotics, have an important role to play in the treatment of psychosis and behavioral dyscontrol in AD, other types of dementia, and other neurodegenerative conditions. Antipsychotics remain the first-line treatment for schizophrenia and other psychotic disorders across the life span. When antipsychotic medications are used in elderly patients, monitoring of target symptoms, somatic side effects, potential drug interactions, cognition, and activities of daily living is necessary.

Chapter 66. Treatment of Chronic Pain Syndromes

TREATMENT OF CHRONIC PAIN SYNDROMES: INTRODUCTION

Pain is the most common symptom reported in both the general population and the general medical setting (Kroenke 2003b; Sternbach 1986; Verhaak et al. 1998). Pain complaints account for more than 40% of all symptom-related outpatient visits, or over 100 million ambulatory encounters in the United States alone each year (Schappert 1992). Pain costs the United States more than $100 billion each year in health care and lost productivity (Stewart et al. 2003). Pain medications are the second most commonly prescribed class of drugs (after cardiac-renal drugs), accounting for 12% of all medications prescribed during ambulatory office visits in the United States (Turk 2002). Yet nonopioid analgesics fail to provide adequate relief in many patients (Curatolo and Bogduk 2001), and physicians' concerns about regulatory restrictions as well as risks of tolerance or addiction constrain the prescribing of opioid analgesics for noncancer pain (Joranson et al. 2002). Moreover, opioids themselves may produce only moderate reductions in chronic pain (Furlan et al. 2006; Martell et al. 2007; Turk 2002) and may fail to improve (or may even worsen) psychological outcomes (e.g., depression) or functional status even when they do alleviate the pain (Moulin et al. 1996). At the same time, clinicians are being pressured to respond to pain as the "fifth vital sign" (Joint Commission on Accreditation of Healthcare Organizations 2000). In House Resolution 1863, the National Pain Care Policy Act of 2003, Congress declared this the "Decade of Pain Control and Research." Indeed, persistent pain is a major international health problem (Gureje et al. 1998), prompting the World Health Organization to endorse a global campaign against pain (Breivik 2002). Persistent pain may lead to excessive surgery or other expensive or invasive procedures and is the leading reason for use of complementary and alternative medicine (CAM) (Astin 1998). Pain is also among the most common reasons for temporary as well as permanent work disability (B. H. Smith et al. 2001). Many pain treatment recommendations are based principally on expert consensus rather than on clinical trial results (Bair et al. 2005) and have yet to influence primary care practice (Chodosh et al. 2001).

PSYCHIATRIC COMORBIDITY

Pain is even more prevalent in patients with psychiatric comorbidity, particularly mood disorders. The overlap between pain and depression ranges from 30% to 60% (Ang et al. 2006; Bair et al. 2003; Magni et al. 1993). Pain is a strong predictor of both the onset and persistence of depression (Ohayon and Schatzberg 2003), and depression is likewise a powerful predictor of pain, particularly persistent pain (Bair et al. 2003; Gureje et al. 1998). Concurrent pain and depression have a much greater impact than either disorder alone on multiple domains of functional status as well as health care utilization (Bair et al. 2003). Comorbid depression worsens disability and decreases active coping in patients suffering from pain (Arnow et al. 2006; Demyttenaere et al. 2006). Comorbidity decreases the likelihood of a favorable response of either condition to treatment and also diminishes patient satisfaction with treatment (Bair et al. 2004; Karp et al. 2005; Kroenke et al. 2008; Mavandadi et al. 2007; Thielke et al. 2007). Thus, reliable methods for assessing the presence and severity of pain in patients with depression (particularly those not responding to initial treatment) and strategies for effectively and efficiently integrating evidence-based depression care into the management of patients with chronic pain are sorely needed (Kroenke 2003a).

Although not as extensively studied, the comorbidity of pain with anxiety appears to be nearly as strong as its comorbidity with depression (Kroenke 2003b; Kroenke and Price 1993; Kroenke et al. 1994, 1997; McWilliams et al. 2003). Indeed, a global study conducted by the World Health Organization in 17 countries involving more than 85,000 community-dwelling adults showed that pain is associated with mood and anxiety disorders, but not with alcohol abuse or dependence (Gureje et al. 2008). The prevalence of specific mood and anxiety disorders was lowest among persons with no pain, intermediate among those with one pain site, and highest among those with multiple pain sites. Relative to persons not reporting pain, the age–sex adjusted odds ratios were 1.8 (95% confidence interval [CI] = 1.7–2.0) for mood disorders and 1.9 (95% CI = 1.8–2.1) for anxiety disorders for persons with single-site pain, and 3.7 (95% CI = 3.3–4.1) for mood disorders and 3.6 (95% CI = 3.3–4.0) for anxiety disorders among those with multisite pain.

DEFINITION AND CLASSIFICATION OF PAIN

The International Association for the Study of Pain (IASP) defines pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage." Although there

are more complex approaches to classifying pain, a pragmatic and frequently used system broadly classifies pain as either *nociceptive* or *neuropathic* (Basbaum et al. 2005). Nociceptive pain includes most cases of acute pain in which a strong, noxious stimulus impacts the skin or deep tissue. Acute pain resolves after the noxious stimulus has been removed, but inflammatory and other mechanisms may lead to persistence of nociceptive pain for weeks, months, or years (i.e., chronic pain). Many pain conditions, including arthritis and other musculoskeletal disorders, migraine and tension headache, and chronic widespread pain conditions such as fibromyalgia, would be classified under the broad rubric of nociceptive pain.

A second type of chronic pain, neuropathic pain, arises from injury to the peripheral or central nervous system. Examples include postherpetic neuralgia, painful diabetic neuropathy, phantom limb pain, and sciatica. Neuropathic pain is often characterized as burning, paroxysmal, stabbing, buzzing, or electric shock–like. Some conditions, such as low back pain, may include both nociceptive components (arising from the muscles or contiguous tissues) and neuropathic components (radicular pain or sciatica).

Persons with chronic pain often suffer from spontaneous ongoing pain. Also, stimuli that are normally not painful (movement, light touch) become painful, a phenomenon known as *allodynia.* Examples include pain produced by touching sunburned skin or moving an arthritic joint. *Hyperalgesia* is exacerbated pain produced by a stimulus that is expected to be only mildly painful (e.g., slapping sunburned skin). These phenomena may be related to central sensitization, which has been proposed as a common mechanism underlying unexplained pain syndromes such as fibromyalgia.

Sometimes, the broader category of nociceptive pain is subclassified into *somatic* pain (triggered in the skin, muscles, joints, or fascia) and *visceral* pain (heart, lungs, gastrointestinal or genitourinary system, or other deeper organs). The latter is diffuse and poorly localized, reflecting differences in innervation between somatic and visceral tissue. Somatosensory fibers are precisely located in the spinal cord and brain, whereas afferent viscerosensory fibers overlap each other and converge at several levels within the nervous system. Although some of the principles of pain management are relevant to visceral pain, in this chapter we concentrate on the management of chronic pain due to nociceptive pain of the somatic variety and neuropathic pain conditions. Together, these account for the majority of chronic pain conditions seen in clinical practice. Moreover, visceral pain is more commonly a harbinger of a serious underlying disorder with specific treatments targeting the disease itself rather than mere analgesia. In contrast, pain itself becomes the primary "disease" or target of therapy in a large proportion of chronic somatic and neuropathic pain disorders.

TREATMENT OF PAIN

Overview

The focus of this chapter is twofold. First, we discuss major classes of medications as they relate to pain management. Because a number of drugs are effective across multiple types of pain disorders, it is useful to consider them in a cross-cutting as well as a disease-specific fashion. Nonpharmacological treatments are also reviewed. In the following main section ("Selected Pain Disorders"), we briefly address several specific categories of disorders chosen because they 1) account for the most common types of chronic pain, 2) are conditions for which pain management is the principal focus, and 3) have been studied in numerous clinical trials. In short, prevalence, pain management as a priority rather than disease modification, and evidence-based therapy are the three selection criteria for the discussion of specific disorders. Even within these two broad foci (disorders and treatments), there will perforce be some intermingling. For example, certain drug classes have been heavily studied within certain pain disorders, and conversely, certain pain disorders have been a common target of several classes of medications or other treatments.

The prototypical diseases discussed are musculoskeletal disorders (principally fibromyalgia, low back pain, and osteoarthritis) and neuropathic pain. Musculoskeletal disorders account for more than two-thirds of pain-related outpatient visits, and neuropathic pain not only is common but also is a popular target for clinical trials in pain management and therefore a common reason for seeking U.S. Food and Drug Administration (FDA) approval of pain as a drug indication. Although pharmacotherapy receives the greatest attention in this chapter, we briefly review nonpharmacological treatments due to their important role in the management of chronic pain. Acute pain (e.g., injuries, postoperative pain), cancer pain, headache, and visceral pain are not addressed. Although a moderate amount of the information presented in this chapter is relevant to the treatment of pain in these and other conditions (especially the discussion of specific analgesics), a detailed discussion of these specialized topics is beyond the scope of this chapter.

Strength of Evidence

The majority of the information in this chapter was derived from meta-analyses and systematic reviews published since 2005. Individual randomized, controlled trials (RCTs) are not presented unless they reported on a promising

treatment for which multiple trials had not yet been performed. Certainly, evidence is strongest for those treatments that have shown efficacy in multiple trials rather than a single RCT, particularly because individual trials sometimes yield contradictory findings. Uncontrolled or open-label studies provide still weaker evidence and are cited only in a few instances.

In meta-analyses and systematic reviews, the magnitude of a treatment's effect on particular domains such as pain and physical function is often reported as an *effect size*. The effect size is a standard way to determine the degree of improvement (or change) related to a particular therapy compared with a placebo or other type of control group. The effect size is calculated as the mean change in the treatment group minus the mean change in the control group, divided by the pooled standard deviation. By convention, an effect size of less than 0.2 is considered trivial; 0.2–0.5, small; 0.5–0.8, moderate; 0.8–1.2, important; and 1.2 or greater, very important (Cohen 1998).

Effect size can be useful when comparing continuous variables such as mean differences (e.g., in pain scores). When comparing response rates on a categorical variable (e.g., "improved" or "≥50% reduction in pain"), the *number needed to treat* (NNT) is another common metric. The NNT is calculated as the reciprocal of the absolute difference between treatment groups. For example, if a clinical trial demonstrates that 60% of subjects improve while taking a new analgesic versus 35% of subjects receiving a placebo, that is an absolute difference of 25%. The NNT is the reciprocal of that: 1/0.25 = 4. This means that for every four patients who receive the analgesic, one additional patient would achieve a therapeutic response over and above placebo (i.e., the other three patients may have done just as well taking the placebo). Actually, an NNT of ≤5 typically represents a reasonably good analgesic.

When studying the same pain condition, the NNT may also be useful in comparing different drugs. For example, in one study of acute pain after certain operative procedures, 10 mg of morphine, 30 mg of ketorolac, and 100 mg of meperidine (all administered by intramuscular injection) and 1,000 mg of acetaminophen (administered orally) all had NNTs between 3 and 4; furthermore, their 95% confidence intervals overlapped, implying no significant difference in the analgesic efficacy between intramuscular opioids, intramuscular nonsteroidal anti-inflammatory drugs (NSAIDs), and oral acetaminophen (Barden et al. 2004). However, analgesic effect may depend on the type of pain condition being treated or clinical context as well. For example, one study found that the NNT for acetaminophen after dental extraction was 3.8, compared with 1.9 after orthopedic surgery (Barden et al. 2004). Also, small sample sizes may affect the precision of NNT estimates; some feel that NNT calculations based on trial data involving fewer than 500 subjects should be interpreted cautiously. Second, it is more problematic to compare the NNTs of different drugs estimated from separate studies than when NNTs are estimated for different drugs tested in the same clinical trial. Third, NNTs derived from studying analgesics in acute pain conditions may not be readily generalizable to their efficacy in the treatment of chronic pain.

Pharmacotherapy

Nonopioid Analgesics

The anti-inflammatory properties of the extract of willow bark have been known for centuries. Salicylic acid was discovered as the extract's active ingredient in the nineteenth century and was subsequently acetylated to improve its gastrointestinal tolerability; acetylsalicylic acid became the prototypical analgesic aspirin. Aspirin and other related compounds constitute a class of drugs known as NSAIDs. All NSAIDs have three desirable pharmacological effects —anti-inflammatory, analgesic, and antipyretic. NSAIDs and acetaminophen are among the most commonly prescribed medications for acute and chronic pain and can also be obtained without a prescription.

Acetaminophen has analgesic and antipyretic effects similar to those of the NSAIDs but lacks a specific anti-inflammatory effect. Despite its widespread use, the analgesic mechanism of acetaminophen is poorly understood. Acetaminophen is a slightly weaker analgesic than NSAIDs (<10 point difference on a 100-point visual analog pain scale) (Lee et al. 2004; Towheed et al. 2006; Wegman et al. 2004) but is a reasonable first-line option because of its more favorable safety profile and low cost. However, acetaminophen is associated with asymptomatic elevations of aminotransferase levels at dosages of 4 g/day even in healthy adults, although the clinical significance of these findings is uncertain (Watkins et al. 2006).

NSAIDs block the enzymatic activity of cyclo-oxygenase (COX), which uses arachidonic acid to generate prostanoids. Prostanoids influence immune, cardiovascular, gastrointestinal, renovascular, pulmonary, central nervous system, and reproductive function. Although gastrointestinal adverse effects have traditionally been considered the most common and worrisome complication, cardiovascular risk has gained increasing attention (Antman et al. 2007). Aspirin was the first and at one time the most commonly used NSAID.

There are two major COX isoenzymes: COX-1 is expressed constantly in most tissues, whereas COX-2 is induced by inflammation. NSAIDs vary in their chemical structure and relative ability to block the COX-1 versus the COX-2

isoenzymes. Several prostaglandins are both hyperalgesic and gastroprotective. Thus, nonselective COX inhibition with NSAIDs like aspirin, ibuprofen, indomethacin, and naproxen, which inhibit both COX-1 and COX-2 enzymes, provides effective pain relief for inflammatory conditions but carries a risk for erosive gastritis and gastrointestinal bleeding. Selective COX-2 inhibitors (valdecoxib, rofecoxib, celecoxib) have less gastrointestinal toxicity because of the relative paucity of COX-2 expression in the gastrointestinal tract relative to inflammatory tissue. However, data from meta-analyses and registries have shown an increased risk of cardiovascular events and mortality from COX-2 use, particularly in patients with known cardiovascular disease who receive prolonged treatment. Rofecoxib (Vioxx) has been withdrawn from the market, and all COX-2 inhibitors should be used cautiously, if at all, in patients with cardiovascular disease or risk factors for cardiovascular disease. All NSAIDs, including nonselective COX inhibitors and COX-2 agents, appear equally effective in the treatment of pain disorders (Chou et al. 2006). The NSAID that appears to be the safest in terms of cardiovascular risk is naproxen.

Opioid Analgesics

> The analgesic effects of opium have been known to mankind for more than 5,000 years. However, their inherent risk of abuse soon became evident. Ever since, society has attempted to find a balance between licit and illicit use, therapeutic versus adverse effects, and medical needs and legal issues. Despite all the legal, administrative, and social interference, no other class of drugs has remained in use for as long as opioids. (Schug 2005)

Opioids have a leading place in the treatment of acute pain and advanced cancer pain of moderate to severe intensity, because in both instances treatment is expected to be of short to medium duration. In contrast, opioid treatment for chronic noncancer pain is frequently delayed until first- or second-line treatments have failed because of less clarity about the benefits of chronic use and greater concerns about addiction, long-term effects (e.g., immunological, reproductive), opioid-induced hyperalgesia, and regulatory difficulties.

The Controlled Substances Act of 1970 divided substances to be regulated into five schedules, as determined by the U.S. Drug Enforcement Administration. These schedules govern the legal distribution and use of most substances with a significant abuse liability. Schedule I drugs have the highest abuse potential; they are available for research only and have no approved medical uses. Schedule II–IV substances have decreasing abuse liabilities (II is the highest) and approved medical uses. Physicians are licensed to prescribe these compounds, and pharmacies can dispense them, although pharmacies do not stock all of these substances. Schedule II compounds have more stringent record-keeping and storage requirements than do Schedule III and Schedule IV substances. Schedule V substances have a recognized abuse liability (and approved medical uses) but are generally not as highly regulated vis-à-vis record keeping. Many of these substances are used in common over-the-counter medicines. Including compounds on this schedule facilitates state and local regulations deemed appropriate in some jurisdictions (e.g., an individual state may impose restrictions on some substance considered to have an unexpectedly high abuse liability).

Propoxyphene and tramadol

Two drugs are "on the border" of what are traditionally considered opioids. Propoxyphene is a lower-scheduled drug than other opioids, and tramadol has been an unscheduled drug. Still, the efficacy and toxicity of both drugs are related, at least in part, to opioid effects, and thus they are discussed within this category.

Propoxyphene (Darvon) had, until recently, been one of the most widely prescribed analgesics for mild to moderate pain. It is often used in combination with acetaminophen (as Darvocet) or aspirin (Darvon Compound). Experts increasingly advise against its use for several reasons (Pasero et al. 1999). First, its therapeutic–toxicity ratio is not particularly favorable. Propoxyphene is only one-half to one-third as potent as codeine. Its recommended dose of 100 mg is equal in analgesic effect to 60 mg of codeine, which is known to be equal to 600 mg (less than two 325-mg tablets) of aspirin. Yet at equianalgesic doses, propoxyphene has the same incidence of minor side effects as codeine. More importantly, propoxyphene and its active metabolite, norpropoxyphene, can accumulate in the body and produce severe toxicity with repeated doses. Respiratory depression, sedation, and cognitive impairment can occur with excessive accumulation or when propoxyphene is used in combination with alcohol or sedating medications, and elderly patients may be particularly sensitive due to poorer renal clearance.

Tramadol (Ultram) is unique in that it has both opioid and nonopioid effects. Although its mode of action is not completely understood, it exerts an analgesic effect through binding to the μ opioid receptor as an agonist (opioid effect) and weakly inhibiting the reuptake of serotonin and norepinephrine (nonopioid effect), similar to the effect of tricyclic antidepressants (TCAs). Tramadol is available in both short- and long-acting formulations. The starting dosage for the short-acting formulation is 50 mg once or twice daily, with gradual titration to a maximum of 400 mg/day. Dosage reduction is necessary in those with renal or hepatic disease. The risk of respiratory depression and, presumably, addiction is lower than with other opiates. Because tramadol is an unscheduled drug, clinicians may not be aware of its opioid effect. However, it still should be used with some caution in persons recovering from substance

use disorders. Dose reduction is recommended in older adult patients (>75 years) and in those with renal impairment (creatinine clearance <30 mL/minute) or cirrhosis of the liver. Multiple trials have demonstrated the efficacy of tramadol in pain disorders, particularly osteoarthritis, fibromyalgia, and neuropathic pain.

Hollingshead et al. (2006) conducted a systematic review of six trials evaluating tramadol in neuropathic pain. All four trials comparing tramadol with placebo showed benefit with tramadol: the NNT with tramadol versus placebo to reach at least 50% pain relief was 3.8. Single trials comparing tramadol with clomipramine or morphine were inconclusive.

In summary, the clinical trial evidence across a number of pain disorders is much stronger for tramadol, which has led to its recommendation as at least a second-line treatment for conditions such as osteoarthritis, fibromyalgia, and neuropathic pain. In contrast, the benefits of propoxyphene have not been clearly shown to exceed its potential risks.

Efficacy of opioids

Furlan et al. (2006) conducted a meta-analysis of opioid use for chronic noncancer pain. Included were 41 trials involving 6,019 patients: 80% of the patients had nociceptive pain (osteoarthritis, rheumatoid arthritis, or back pain); 12%, neuropathic pain (postherpetic neuralgia, diabetic neuropathy, or phantom limb pain); 7%, fibromyalgia; and 1%, mixed pain. For certain analyses, the authors classified opioids as weak (propoxyphene, tramadol, codeine) and strong (all other opioids). Tramadol was the agent studied in 17 trials (3,433 patients), propoxyphene or dextropropoxyphene in 3 trials (1,074 patients), codeine in 7 trials (444 patients), oxycodone in 6 trials (517 patients), and morphine in 8 trials (551 patients). Average duration of treatment was 5 weeks (range, 1–16 weeks). On average, 33% of patients in the opioid groups dropped out (15% because of inadequate pain relief and 21% because of side effects; some patients reported both reasons), as did 38% in the placebo groups (30% because of inadequate pain relief and 10% because of side effects).

Opioids were more effective than placebo for both pain and functional outcomes in patients with nociceptive or neuropathic pain. The only opioid studied for fibromyalgia was tramadol (2 trials, 228 patients), where it proved effective. The effect size for opioids compared with placebo was moderate for pain (–0.60) and small for functional outcomes (–0.31). Only 8 trials compared opioids with other analgesics; in these trials, opioids did not differ significantly from nonopioids in terms of pain relief (effect size, –0.05) and were significantly worse than nonopioids in terms of functional outcomes, although only slightly so (effect size, 0.16). The authors concluded that the strong opioids (oxycodone, morphine) were significantly more effective than other drugs (effect size, –0.34), but this was based on only 2 trials, one of which was an open-label study (Furlan et al. 2006).

A systematic review reported on 11 studies (2,877 patients) that assessed quality of life in patients with chronic nonmalignant pain receiving long-term opioid treatment (Devulder et al. 2005). Six studies were randomized trials and five were observational studies. Of the 4 trials in which baseline values were reported, 3 showed an improvement in quality of life. Similarly, it improved in 4 of the 5 observational studies. While this suggests potential quality-of-life benefits, the authors concluded that further methodologically rigorous studies are needed to confirm these findings and to elucidate the potential adverse effects of physical tolerance, withdrawal, and addiction on functional status.

Adverse effects

Moore and McQuay (2005) conducted a systematic review of 34 trials with 4,212 patients that provided information on adverse events related to opioid use in treating noncancer pain. Most opioids used (accounting for 90% of patients) were for treating moderate rather than severe pain. Dry mouth (affecting 25% of patients), nausea (21%), and constipation (15%) were the most common adverse events. A substantial proportion of patients taking opioids (22%) withdrew because of adverse events. Because most trials were short (<4 weeks) and did not use titrated doses, the implications for long-term use in clinical practice are less certain. Eisenberg et al. (2006) also reported on adverse events in their systematic review of opioids for neuropathic pain. Compared with placebo recipients, opioid recipients had higher rates of nausea (33% vs. 9%), constipation (33% vs. 10%), drowsiness (29% vs. 12%), dizziness (21% vs. 6%), and vomiting (15% vs. 3%). Among studies reporting causes of withdrawal, more patients receiving opioids withdrew because of adverse effects (11% vs. 4%). Finally, in the review by Furlan et al. (2006), only three side effects occurred significantly more frequently with opioids than with placebo: nausea, constipation, and somnolence. These rates were 14%, 9%, and 6% higher in opioid recipients, respectively.

A large population-based study from Denmark found that opioid usage was significantly associated with more severe pain, poorer self-rated health, lower quality of life, less physical activity, lower employment, higher levels of health care utilization, and more subjects living alone (Højsted and Sjøgren 2007). The cross-sectional nature of the study does not prove causation, and it is certainly possible that the opioid users would have fared worse without opioid treatment. However, it does raise questions of whether opioid treatment of chronic pain is achieving the key goals of pain relief, improved functional status, and better quality of life.

Studies have indicated that endocrinological abnormalities such as hypogonadism and erectile dysfunction may be associated with opioid therapy (Ballantyne and Mao 2003; Daniell 2002). In women, opioid use has been associated with amenorrhea and decreased sex hormone levels (Daniell 2008). Two small trials evaluating opioid use in chronic pain reported analyzable data regarding sexual activity, and both found that patients taking opioids had better self-reported sexual function than those taking placebo (Furlan et al. 2006). Improvement of well-being secondary to better pain control may account for this. Clearly, the incidence and clinical significance of opioid-related hypogonadism need to be better defined.

A feared consequence of long-term opioid use is cognitive dysfunction. Studies have suggested that opioid treatment for chronic pain may be associated with impaired neuropsychological performance regarding reaction times, psychomotor speed, and working memory (Højsted and Sjøgren 2007). However, many other factors may be playing a role, including pain itself, concomitant medications, and psychiatric comorbidity. A systematic review concluded that stable doses of opioids do not impair driving performance (Fishbain et al. 2003).

Tolerance and addiction

The risks of prescription opioid addiction, abuse, and diversion among chronic pain patients are not well understood. In part, this is due to inconsistent use of terminology and the difficulty of defining addiction and abuse in patients receiving opioids for chronic pain (Heit 2003; Savage et al. 2003). The term *dependence* is particularly problematic because confusion can occur between physical dependence, psychological dependence, and substance dependence (as defined in DSM-IV-TR [American Psychiatric Association 2000]). Some experts believe that the term *addiction* should be reserved for the specific condition defined as substance dependence in DSM-IV-TR. *Misuse* describes other problematic opioid use, including DSM-IV-TR substance abuse and other nontherapeutic uses that do not meet DSM-IV-TR criteria. *Diversion* includes selling, sharing, and trading of prescription opioids.

A systematic review of the literature on the risk of iatrogenic addiction in patients treated with opioids for acute and subacute pain yielded 41 eligible articles (Wasan et al. 2006). However, there were no randomized trials or comparative longitudinal studies, and the results of nine studies of low methodological quality yielded conflicting findings. The authors concluded that it is not known whether the risk for iatrogenic addiction among patients treated for acute or subacute pain is relatively high (>10%) or low (<0.1%).

In a 10-year follow-up study of patients treated with opioids for chronic pain, tolerance was not a problem in the majority of patients (Jensen et al. 2006). In contrast, a retrospective study of 104 chronic pain patients younger than 50 years and 102 patients older than 60 years showed that younger patients and those with nociceptive pain (as compared with neuropathic pain) had much higher escalation of opioid doses over a 15-month follow-up period (Buntin-Mushock et al. 2005). Another worrying finding of this study was that although the younger patients had a dosage increase of 640% (from 49 to 365 mg/day of morphine equivalent) during the observation period, the pain visual analog scale scores did not change at all. Although this does not mean that addiction is playing an important role, it does suggest that decisions about dose escalation may need to vary depending on the type of pain, patient age, treatment response, and other factors. Failure of pain to improve with moderate dosage increases in an individual patient may indicate that opioids are not the optimal treatment rather than that continuing dose escalations are needed. Some experts have classified patients or pain syndromes as opioid responsive versus opioid resistant (H. S. Smith 2005). Indeed, some patients may develop opioid-induced hyperalgesia where the balance between anti-nociceptive and pro-nocioceptive systems is upregulated after opioid exposure, leading to an enhanced vulnerability to pain (Angst and Clark 2006; Højsted and Sjøgren 2007).

Højsted and Sjøgren (2007) reviewed some important predictors of opioid use. The "rush" the patient experiences after administration of an opioid is caused by a rapid and large increase in dopamine in the brain reward system. Important factors for abuse liability associated with the drug include the speed of access and the concentration at the target sites. On a scale of opioid attractiveness, sustained-release oxycodone had the highest rating and the fentanyl patch had the lowest score; oral transmucosal fentanyl, methadone, and sustained-release morphine had intermediate scores. However, research demonstrating higher abuse potential of one opioid versus another is limited. Risk factors for opioid abuse in patients with chronic pain are young age, male gender, past alcohol or cocaine abuse, previous drug conviction, mental health disorders, pain in multiple regions, and pain after motor vehicle accidents.

A randomized trial of 11,352 participants with chronic noncancer pain compared the abuse potential of tramadol, NSAIDs, and hydrocodone (Adams et al. 2006). Abuse was defined by an algorithm including increasing doses without physician approval, use for purposes other than the ones intended, inability to stop using the drug, and withdrawal. The percentage of subjects who scored positive for abuse at least once during the 12-month follow-up period was 2.5% with NSAIDs, 2.7% with tramadol, and 4.9% with hydrocodone. When more than one algorithm criterion was required, abuse rates were 0.5% with NSAIDs, 0.7% with tramadol, and 1.2% with hydrocodone. Although the

authors concluded that the prevalence of abuse/dependence was significantly less with NSAIDs and tramadol than with hydrocodone, the rates are overall quite low and the between-group differences are rather small.

General principles of opioid use

Useful suggestions for management of chronic opioid therapy have been published (Ballantyne 2006; Kahan et al. 2006; Pasero et al. 1999). The use of very high doses of opioids is rarely helpful. Purely on the basis that the highest daily dosage of opioids used in existing trials is 180 mg of morphine or its equivalent, opioid reduction or rotation should be considered at this point. Because of incomplete cross-tolerance (i.e., patients may be tolerant to high doses of the first opioid yet have a lower tolerance to the new opioid), the initial dosage of a new opioid should be equivalent to 50% or less of the dosage of the original opioid. Equianalgesic doses of oral and transdermal opioids are summarized in Table 66–1. When trials of several opioids are ineffective in chronic pain, it is appropriate to consider weaning patients off the drug and discontinuing its use. Weaning can usually be accomplished over 10 days, but the exact weaning schedule depends on dose, drug, and duration of treatment. In cases of addiction, referral to an addiction specialist may be preferable to drug discontinuation. Opioids are often best used as an adjunctive treatment rather than as the sole therapy for chronic pain. Before starting opioid therapy, patients should understand that the goal of treatment is not the complete elimination of pain but a 25%–50% reduction in its intensity and improvement in mood and functioning.

TABLE 66–1. Oral and transdermal opioid analgesic equivalence

Drug	Dose (mg)	Duration (hours)[a]
Morphine	20–30	2–4
Codeine	200[b]	3–4
Hydrocodone	30[c]	4–6
Oxycodone	20	3–4
Hydromorphone	7.5	3–4
Meperidine	300[b]	2–4
Methadone	20[d]	4–8
Fentanyl (transdermal)	0.001/hour (1 μg/hour)[e]	48–72

[a]Duration of analgesia is dose-dependent; the higher the dose, usually the longer the duration.

[b]These high doses of codeine and meperidine are not recommended clinically.

[c]Equianalgesic data not available for hydrocodone.

[d]For opioid-tolerant patients converted to methadone, starting doses should be 10%–25% of the equianalgesic dose. Also, the half-life of methadone can vary widely, from 12 to 190 hours.

[e]1 μg/hour transdermally is approximately equal to morphine 2 mg/24 hours orally.

Whether patients at risk for addiction should be excluded from opioid therapy is controversial. Current evidence suggests that such patients do well in controlled programs and should not be denied opioid treatment of pain solely on the basis of existing addiction comorbidities. A written agreement may be helpful for obtaining informed consent about the risks and benefits of opioid therapy and setting out terms of use, including the following:

- Obtaining opioids only from a single provider
- Reporting lost or stolen drugs promptly
- Not using more than is prescribed or requesting early refills on a regular basis
- Testing urine periodically to determine that opioids are being taken by the patient (and not diverted for economic gain) and that illicit drugs are not being taken

Some experts recommend a universal precautions approach for all patients receiving opioids because clinical factors are not sufficiently predictive of who will have problems with abuse or addiction. At each visit, the clinician should document the "4 *A*s" (McCarberg and Passik 2005):

- Analgesic (pain relief)
- Activities of daily living (physical and psychosocial functioning)
- Adverse effects (side effects)
- Aberrant drug taking (taking more than prescribed, diversion, etc.)

Long-acting opioids

Chou (2008) conducted an evidence-based review of 25 randomized trials (*N* = 2,752) that evaluated long-acting opioids in patients with chronic noncancer pain. The review included 2 or more clinical trials of transdermal fentanyl and long-acting oral oxycodone, morphine, codeine, and dihydrocodeine. Methadone and levorphanol were each studied in only a single trial, and no trials evaluated long-acting hydromorphone. Only 5 trials compared one long-acting opioid with another; 7 compared a long-acting opioid with a short-acting opioid, and 13 compared a long-acting opioid with a nonopioid agent or placebo. Ten trials used a crossover design. The number of subjects in the trials averaged 110 (range, 12–680). The pain disorder was osteoarthritis in 5 trials, back pain in 7, neuropathic pain in 7, heterogeneous pain conditions in 4, phantom limb pain in 1, and chronic pancreatitis in 1. Nearly all of the trials were of relatively short duration, ranging from 5 days to 16 weeks. All trials excluded persons with past or current substance abuse. The majority of trials recruited patients from specialty clinics, most commonly from rheumatology or pain practices.

The authors concluded that there is insufficient evidence from either the 20 trials comparing long-acting opioids with other types of drugs or with placebo or the 5 head-to-head trials to suggest that one long-acting opioid is superior to another. The largest (680 subjects) and longest (13 months) randomized trial found that transdermal fentanyl and twice-daily morphine were similar in efficacy for patients with chronic low back pain who had not previously received strong opioids on a regular basis (Allan et al. 2005). Also, the 7 trials comparing long- versus short-acting opioids were unable to demonstrate superior efficacy or lesser side-effect rates with long-acting opioids. The single fair-quality trial comparing differences in adverse events among long-acting opioids found less constipation with fentanyl than with morphine (31% vs. 48%) but also a trend toward a higher rate of withdrawals due to any adverse event with fentanyl (37% vs. 31%).

Methadone

Until recently, methadone has been used primarily as maintenance drug to prevent withdrawal in opioid-addicted adults. The stigma as a "drug for addicts" has been one factor limiting its use as an analgesic in clinical practice. It has gained increased use in the treatment of intractable pain in end-of-life care and other palliative care settings. Concerns regarding use of methadone for pain relate to its long and unpredictable half-life and the associated risk of a delayed overdose. Furthermore, there are large individual variations in presumed equianalgesic doses of methadone relative to other opioids. This prevents the use of simple equianalgesic tables to calculate the required dose of methadone during rotation from other opioids.

Although methadone has increasingly been used for the treatment of chronic noncancer pain, published data are rather modest. In a literature review of 21 studies, only 1 small randomized trial (*N* = 19) was found; the remainder were either cases series (*N* = 7) or case reports (*N* = 13) (Sandoval et al. 2005). Methadone was administered primarily when previous opioid treatment was ineffective or poorly tolerated. Thus, the evidence base is currently inadequate and does not support a first-line role for methadone in chronic pain therapy.

Antidepressants

Tricyclic antidepressants and selective serotonin reuptake inhibitors

TCAs have the longest track record in the treatment of multiple pain conditions. Typically, lower doses of TCAs have been used in clinical trials of pain (e.g., 25–100 mg of amitriptyline or equivalent) than the doses usually necessary for treating depression. Advantages of TCAs include good evidence from multiple clinical trials, decades of clinical experience with TCAs in pain management, and the low cost of these generic agents. Disadvantages include the side effects associated with TCAs (which may be less, however, when prescribing the lower doses used for analgesia), including worrisome cardiovascular side effects (e.g., hypertension, postural hypotension, arrhythmias) and a risk of falling in elderly patients, and potential lethality in overdoses.

A meta-analysis of 96 RCTs evaluating antidepressants for the treatment of conditions manifested by somatic symptoms (the majority involving painful symptoms) included 55 TCA trials, of which 76% showed benefits; 28 trials using anti-serotonin agents (principally headache trials using mianserin, a drug approved in Europe but not in the United States), of which 57% showed benefits; and 17 trials using selective serotonin reuptake inhibitor (SSRI) antidepressants, of which 47% showed positive results (O'Malley et al. 1999). Only a few trials were head-to-head comparisons of two antidepressants. Indirect comparisons did not show a significant difference by type of antidepressant using meta-regression, but TCAs were superior to SSRIs ($P < 0.02$) using a bivariate tally procedure. Admittedly, such statistical comparisons are not as conclusive as direct comparisons of antidepressants within the same trial. Another review concluded that SSRIs appeared to have a relatively weak effect in ameliorating chronic pain (Jung et al. 1997).

Serotonin–norepinephrine reuptake inhibitors

Duloxetine has proven superior to placebo in three 12-week randomized, placebo-controlled trials that enrolled patients with pain due to diabetic peripheral neuropathy (Goldstein et al. 2005; Raskin et al. 2005; Wernicke et al. 2006). Both 60-mg and 120-mg daily dosages of duloxetine separated from placebo, but not from one another. Duloxetine showed no adverse effects on diabetes control. Duloxetine showed rapid onset of action, with separation from placebo beginning at week 1. Both patients with depression and those without depression were enrolled in the trials, although path analysis estimated that more than 90% of the analgesic effect in duloxetine-treated patients with diabetic neuropathy was attributable to a direct analgesic effect, with less than 10% possibly explained by an antidepressant effect (Perahia et al. 2006).

Some have questioned the strength of the evidence regarding the analgesic effect of serotonin–norepinephrine reuptake inhibitors (SNRIs). A recent meta-analysis of five trials in depressed patients reported a very small and statistically nonsignificant ($P = 0.057$) analgesic effect for duloxetine (Spielmans 2008). Another meta-analysis that examined the evidence comparing duloxetine with SSRIs in treating the painful physical symptoms of depression likewise concluded that there was insufficient evidence of a superior analgesic effect with duloxetine (Krebs et al. 2008b). On the other hand, placebo-controlled trials of duloxetine have shown a significant analgesic effect of duloxetine not only for neuropathic pain but for the chronic widespread pain of fibromyalgia as well (Arnold et al. 2004, 2005, 2007b).

Several factors related to these trials should be considered. Pain was typically examined as a secondary outcome in major depression trials, and an important proportion of patients had no pain. Thus, the depression studies were not optimally designed to test analgesic effects. In contrast, the neuropathic pain and fibromyalgia studies were designed primarily to examine treatment effects on pain. Of note, major depression trials in which the sample was enriched with patients reporting at least moderate pain showed that duloxetine had an analgesic effect that was independent of its effect on depression (Brannan et al. 2005; Brecht et al. 2007). The analgesic effect of duloxetine in the pain trials was compared with placebo rather than with another antidepressant. Head-to-head comparisons of a particular antidepressant with an active comparator are few, so it is harder to draw conclusions about the superiority of duloxetine or other SNRIs compared with other antidepressants or pain treatments. In summary, there is reasonably good evidence that duloxetine is more effective than placebo in treating neuropathic pain and fibromyalgia. Evidence regarding its separation from placebo in treating the secondary painful symptoms of major depression is inconclusive, and its relative effectiveness for pain compared with other antidepressants or analgesic therapies requires head-to-head clinical trials.

Other antidepressants

Mirtazapine was studied in a 6-week open-label trial of 594 patients with a primary diagnosis of at least one chronic pain syndrome (≥3 months) and a clinical diagnosis of depression (Freynhagen et al. 2006). The mean daily dose was 35 ± 10 mg at study endpoint, and a statistically significant reduction in pain ($P < 0.0001$) was found. Pain improvement was not related to age or type of pain syndrome.

Anticonvulsants

Anticonvulsant drugs have been used in the management of pain since the 1960s. The clinical impression is that they are useful for chronic neuropathic pain, especially when the pain is lancinating or burning. Three of the most extensively studied anticonvulsants are gabapentin, pregabalin, and carbamazepine. Gabapentin and pregabalin have the strongest evidence for the treatment of pain. These two *gabapentinoids* act as neuromodulators by selectively binding to the $\alpha_2\delta$-subunit protein of calcium channels in various regions of the brain and the superficial dorsal horn of the spinal cord. This results in inhibition of the release of excitatory neurotransmitters that are important in the production of pain. Gabapentin and pregabalin are analogs of γ-aminobutyric acid (GABA), but they have no activity at GABA receptors and do not alter GABA uptake or degradation.

Gabapentin

A systematic review of 15 trials (1,468 participants) evaluating gabapentin included 1 acute pain trial and 14 trials involving neuropathic pain (7 studies of diabetic neuropathy, 2 of postherpetic neuralgia, and 1 each of cancer-related neuropathy, phantom limb pain, spinal cord injury, Guillain-Barré syndrome, and miscellaneous neuropathies) (Wiffen et al. 2005b). In the 14 chronic neuropathic pain trials, 42% of participants improved taking gabapentin versus 19% taking placebo, and the NNT for improvement in all trials with evaluable data was 4.3 (95% CI = 3.5–5.7). Withdrawal rates were 14% for gabapentin versus 10% for placebo. The study of acute postoperative pain (70 patients) showed no benefit for gabapentin. Thus, there is good evidence that gabapentin is more effective than placebo in the treatment of chronic neuropathic pain.

Pregabalin

Pregabalin is a novel compound that has analgesic, anticonvulsant, and anxiolytic effects (Shneker and McAuley 2005). The FDA approved pregabalin for treatment of neuropathic pain associated with diabetic peripheral neuropathy and postherpetic neuralgia and for treatment of fibromyalgia; evidence from the supporting trials is discussed in the "Neuropathic Pain" and "Fibromyalgia" sections of this chapter. Pregabalin is also approved as an adjunctive therapy for adults with partial-onset seizures. The U.S. Drug Enforcement Administration has placed pregabalin in Schedule V of the Controlled Substance Act (indicating a low potential for abuse), possibly because of withdrawal symptoms that were found during clinical trials. The most common adverse events are related to the central nervous system and include somnolence, dizziness, and peripheral edema. Dose-related weight gain can occur, highest at a dosage of 600 mg/day. For pain disorders, the usual dosage is 300–450 mg/day, administered in twice-daily doses.

Carbamazepine

A systematic review of 12 trials (404 participants) included 4 placebo-controlled trials of trigeminal neuralgia, of which 2 with evaluable data yielded an NNT of 1.8 (95% CI = 1.4–2.8) (Wiffen et al. 2005c). For diabetic neuropathy the data were insufficient to calculate an NNT. There was no evidence that carbamazepine was effective for acute pain. In summary, carbamazepine appears effective for trigeminal neuralgia, but the amount and quality of evidence for gabapentin are stronger for other types of neuropathic pain.

Other anticonvulsants

A systematic review that included other anticonvulsants found an NNT of 2.1 (95% CI = 1.5–3.6) for phenytoin in a single trial of diabetic neuropathic pain (Wiffen et al. 2005a). Sodium valproate was ineffective in a single trial of acute pain.

Other Pharmacological Agents

Skeletal muscle relaxants

Most skeletal muscle relaxants are approved by the FDA for treating either spasticity (baclofen, dantrolene, and tizanidine) or musculoskeletal pain (carisoprodol, chlorzoxazone, cyclobenzaprine, metaxalone, methocarbamol, and orphenadrine) (Chou and Peterson 2005). There is insufficient evidence to prove that skeletal muscle relaxants differ in their efficacy, adverse events, or safety. Most trials have focused on acute rather than chronic pain. Cyclobenzaprine has been studied in several fibromyalgia trials and is discussed further in the "Fibromyalgia" section (under "Pharmacotherapy"). Indeed, cyclobenzaprine is the best-studied muscle relaxant in musculoskeletal disorders overall; in 21 fair-quality trials, it has consistently proven superior to placebo for relieving pain, reducing muscle spasms, and improving functional status. Cyclobenzaprine 5-mg doses are equally effective as 10-mg doses (each given three times a day) but cause fewer side effects. Also, 20-mg doses (thrice daily) are not more effective than 10-mg doses and cause more side effects.

Topical analgesics

A potential advantage of topical agents is avoidance of the systemic side effects often associated with oral medications. Disadvantages are that only localized areas of pain can be effectively treated and that irritating skin reactions occur in a minority of patients. Several topical analgesics—lidocaine, capsaicin, and salicylate—have been studied in multiple trials. Postherpetic neuralgia is an FDA-approved indication for the lidocaine 5% patch, which is discussed in more detail in the "Neuropathic Pain" section. In a meta-analysis of systemic administration of local anesthetics for neuropathic pain, Tremont-Lukats et al. (2005) reviewed 19 studies (706 patients total; 10 trials of lidocaine and 9 trials of mexiletine, an antiarrhythmic agent that is also used off-label for pain). Lidocaine (most commonly 5 mg/kg administered intravenously over 30–60 minutes) and mexiletine (median dosage = 600 mg/day administered orally) were similar in efficacy and tolerance to morphine, amitriptyline, and gabapentin. However, the effects of parenteral lidocaine are short lived, and mexiletine is not yet widely used or recommended as first- or second-line therapy.

Capsaicin is an alkaloid derived from chili peppers that acts on vanilloid type 1 receptors; repeated application of capsaicin is thought to desensitize cation channel receptors, leading to depletion of substance P from primary afferent neurons (Chong and Hester 2007). The main disadvantage of capsaicin is the initial burning sensation, which may persist for days. Capsaicin must be applied three to four times per day over the entire painful area for up to 8 weeks before optimal pain relief can be achieved. Mason et al. (2004a) reviewed the clinical trial evidence for using capsaicin to treat chronic pain. Six double-blind, placebo-controlled trials (656 patients) were pooled for analysis of neuropathic conditions, and three double-blind, placebo-controlled trials (368 patients) were pooled for analysis of musculoskeletal conditions. In patients with neuropathic pain, 57% of patients achieved at least 50% pain relief with capsaicin versus 42% of patients taking placebo. In patients with musculoskeletal conditions, the response rates were

38% versus 25%. Approximately one-third of patients experienced local adverse events with capsaicin. The authors concluded that capsaicin has moderate to poor efficacy in the treatment of chronic musculoskeletal or neuropathic pain but may be useful as an adjunctive therapy or sole therapy for a small number of patients who are unresponsive to, or intolerant of, other treatments.

The same authors also reviewed the evidence for topical salicylate (Mason et al. 2004b). In three trials evaluating 182 patients with acute conditions, topical salicylate was significantly more efficacious in relieving pain than placebo (NNT = 2.1; 95% CI = 1.7–2.8). In six trials evaluating 429 patients with chronic conditions, topical salicylate was also better than placebo (NNT = 5.3; 95% CI = 3.6–10.2). However, larger, more rigorous trials tended to have negative results. Based on limited information, the authors concluded that topical salicylates may be efficacious in the treatment of acute pain, although trials of its use in treating musculoskeletal and arthritic pain suggested moderate to poor efficacy. Finally, systematic reviews (J. Lin et al. 2004; Mason et al. 2004c) as well as a recent RCT suggest that topical NSAIDs may be beneficial (ibuprofen for osteoarthritis of the knee has been studied the most) (Underwood et al. 2008).

Cannabinoids

The presence of specific high-affinity cannabinoid type 1 (CB_1) receptor binding sites has been demonstrated in the central nervous system and in certain peripheral tissues, whereas CB_2 receptors are expressed in high quantities in immune tissues and cells. Two main endogenous cannabinoids have been described, and their role in modulating pain has been increasingly recognized. The social stigma associated with cannabinoids and the politicolegal issues related to cannabis use for medical purposes have been barriers to research.

Nonetheless, six RCTs published since 2005 have shown promising results (Beaulieu and Ware 2007). The largest study enrolled 502 patients with multiple sclerosis; the primary outcome was objective spasticity rather than pain. Five smaller trials involving a total of 217 patients measured short-term outcomes (trial duration, 1–5 weeks) of five different pain conditions, including multiple sclerosis, rheumatoid arthritis, upper motor neuron syndrome, human immunodeficiency virus (HIV) neuropathy, and heterogeneous chronic pain. The agents studied included oral tetrahydrocannabinol in three trials, nabilone in two trials, and smoked marijuana in one trial. Five of the six trials (including the large trial) showed benefits.

In a recent review, Lever and Rice (2007) were more circumspect about the role of cannabinoids in chronic pain:

> Preclinical studies demonstrate that cannabinoids can reduce pain response in a range of inflammatory and neuropathic pain models. In contrast, the clinical effectiveness of cannabinoids as analgesics is less clear. Progress in this area requires the development of cannabinoids with a more favourable therapeutic index than those currently available for human use, and the testing of their efficacy and side effects in high-quality clinical trials. (p. 265)

In summary, cannabinoids can be considered promising at this point but still experimental for the treatment of chronic pain. Despite this, cannabinoids now appear as adjunctive agents in treatment guidelines for neuropathic pain in Europe (Attal et al. 2006) and Canada (Moulin et al. 2007).

Nonpharmacological Treatments

Nonpharmacological treatments will not be discussed in detail but need to be mentioned because of their important role in the management of chronic pain. Medications are typically targeted to the symptoms, but dysfunctional beliefs, attitudes, coping styles, and behaviors frequently develop in patients with chronic pain and contribute to its perpetuation and their disability. Moreover, just as in other chronic medical disorders, pharmacotherapy is necessary but not sufficient for optimizing outcomes. For example, the patient with diabetes not only needs insulin or other hypoglycemic drugs but also requires dietary changes, exercise, and other lifestyle modifications to achieve target blood glucose levels.

Psychotherapy and Behavioral Interventions

Cognitive-behavioral therapy

Cognitive-behavioral therapy (CBT) has by far the largest body of evidence supporting its effectiveness in the treatment of various types of chronic pain disorders. Kroenke and Swindle (2000) reviewed 31 trials of CBT for the treatment of somatic syndromes, of which more than half involved pain conditions, including 5 trials of back pain, 3 of irritable bowel syndrome, 3 of noncardiac chest pain, 2 of fibromyalgia, and 4 of other pain disorders. Most of those trials (14 of 17) involving pain disorders found CBT to be beneficial. A recent update of this review found additional more recent studies confirming the effectiveness of CBT (Jackson et al. 2006). Also, a recent systematic review of treatment for somatoform disorders (in which multiple pain symptoms are often present) found CBT was effective in

11 of 13 RCTs (Kroenke 2007). Both group CBT and individual CBT appeared effective, as did briefer courses of CBT (e.g., 3–6 sessions). When administered for pain and other somatic disorders, it is important that CBT be *somatically focused*, having a somewhat different orientation than CBT provided for depressive and anxiety disorders. Patients with chronic pain and other somatic syndromes present with physical rather than psychological symptoms and often attribute their symptoms to physical disorders (i.e., medical factors). Thus, the mental health professional accustomed to providing CBT for psychiatric disorders may require some additional training in CBT appropriate for treating chronic pain and other somatic syndromes.

Pain self-management programs

Pain self-management (PSM) programs that emphasize self-efficacy have consistently demonstrated effectiveness in improving health outcomes and reducing health care utilization among patients with various rheumatic conditions

Principle	Comments
Structured vs. home based	The benefits of structured exercise programs demonstrated in some research studies may have a "voltage drop" when patients are instructed to begin an exercise program on their own. Exercise conducted in clinical settings (e.g., physical therapy, rehabilitation programs) or community settings (e.g., YMCA, fitness centers) may be reinforced by motivation, group participation, expert leadership, guidance, and/or an externally imposed regular schedule.
Monotherapy vs. bundled	Many studies of exercise have included other components, such as education about the particular pain disorder, self-management techniques, relaxation, and other cognitive-behavioral strategies. Certainly, exercise coupled with one or more of these is ideal.

Complementary and Alternative Medicine

A comprehensive review of CAM therapies for chronic pain was recently published (Tan et al. 2007). Although it is beyond the scope of this chapter to discuss this subject in detail, the authors concluded there was reasonable evidence for the effectiveness of the following therapies:

- Acupuncture for chronic low back pain and probably premenstrual syndrome–related pain
- Massage therapy for low back and shoulder pain
- Chiropractic therapy for several types of musculoskeletal pain
- Yoga for low back pain
- Meditation (as well as hypnosis) for several types of chronic pain

Two CAM treatments in particular—acupuncture and the use of magnets—have been the topic of several recent systematic reviews (Table 66–3). Acupuncture has proven effective in treating back pain and possibly osteoarthritis of the knee, although osteoarthritis trials have been fewer and the results less conclusive (Manheimer et al. 2005, 2007; A. White et al. 2007). Although headache pain is not the focus of this chapter, it should be noted that a systematic review of 13 trials of acupuncture for migraine headaches found inconclusive evidence supporting its efficacy, although most studies had serious design limitations (Griggs and Jensen 2006). Acupuncture's effects on experimental pain appear to be mediated through the release of neurohormonal factors, some of which can be inhibited by the opioid antagonist naloxone (Staud 2007). Compared with the pain relief associated with placebo use, acupuncture-related pain relief takes considerable time to develop and to wear off.

TABLE 66–3. Acupuncture and magnets for painful disorders: summary of systematic reviews

Treatment	Study	Condition	Review type (*N*)	Benefits	Strength of evidence	Comments
Acupuncture						
Acupuncture	Manheimer et al. 2005	Back pain	Meta-analysis (33 trials)	Yes	Good	Acupuncture was more effective than sham acupuncture (ES = 0.54) or no treatment (ES = 0.69) in chronic low back pain.
Acupuncture	Manheimer et al. 2007	Knee OA	Meta-analysis (11 trials)	Mixed	Moderate	Acupuncture was more effective than wait-list (ES = 0.96) or usual-care controls but only slightly more effective than sham acupuncture for short-term (ES = 0.35) and long-term (ES = 0.13) pain improvement.
Acupuncture	A. White et al. 2007	Knee OA or pain	Meta-analysis (13 trials)	Yes	Moderate	In 5 studies that could be combined (*N* = 1,334), acupuncture was superior to sham acupuncture for pain and function and was also superior to no-intervention controls.
Magnetism						
Static magnets	Eccles 2005	Various	Systematic (21 trials)	Yes	Moderate	Eleven of 18 better-quality trials were positive. Multiple types of pain conditions were studied.
Static magnets	Pittler et al. 2007	Various	Meta-analysis (25 trials)	No	Moderate	Meta-analysis showed no significant effects. Evidence was encouraging only for one condition —osteoarthritis.

Treatment	Study	Condition	Review type (*N*)	Benefits	Strength of evidence	Comments
PEMF stimulation	McCarthy et al. 2006	Knee OA	Systematic (five trials)	No	Moderate	PEMF therapy yielded insignificant improvement in pain and function.

Note. ES = effect size (mean difference between groups divided by pooled standard deviation); OA = osteoarthritis; PEMF = pulsed electromagnetic field.

Static magnets represent a multibillion-dollar industry (Pittler et al. 2007). As many as one-quarter of patients with rheumatoid arthritis, osteoarthritis, or fibromyalgia use magnets or copper bracelets for pain relief. The mechanisms for magnets' putative efficacy are not established. One theory is that magnetic fields attenuate nociceptive C-fiber depolarization by shifting the membrane resting potential. Another theory suggests that magnetic fields promote an increase in blood flow through the skin and subcutaneous and muscular tissues, which reduces pain. However, the empirical data for efficacy are inconclusive. A qualitative review found that static magnets were effective across a variety of pain conditions (Eccles 2005). However, a quantitative meta-analysis found no significant effects of static magnets, except possibly (though not conclusively) in treating osteoarthritis (Pittler et al. 2007). Pulsed electromagnetic energy has been much less studied and in a review of five trials was found ineffective (McCarthy et al. 2006).

Combination Therapy

Over time, the treatment of chronic pain often includes stepwise addition to a patient's regimen (and deletion if a therapy shows no benefit) of medications from several classes (Black and Sang 2005; Gallagher 2005). In addition to medications given to produce analgesia, pain management may include medications to treat the side effects of the analgesics, such as laxatives or stool softeners for patients receiving opioids, gastroprotective medications for those receiving NSAIDs, and psychostimulants to combat excessive somnolence.

Very few studies have tested combinations of treatments to determine their additive value, if any, compared with monotherapy. Only limited data suggest that the combination of acetaminophen with NSAIDs has additive pain-relieving effects (Schug 2005). More data show a beneficial effect in combining acetaminophen with opioids, including codeine, tramadol, and morphine. Indeed, one of the more common fixed combinations in a single pill has been the coupling of an opioid, such as codeine, tramadol, oxycodone, or hydrocodone, with a nonopioid analgesic such as acetaminophen or aspirin. One important consideration in using fixed-dose combinations is that the maximum daily dosages of one component may restrict flexibility in optimizing the dosage of the other component. For example, when oxycodone 5 mg is combined with acetaminophen 500 mg, the maximum number of tablets that can be administered is eight in a 24-hour period (i.e., 4,000 mg of acetaminophen). If this is insufficient to manage the patient's pain, the opioid and nonopioid should be given as separate medications to allow further upward titration of the opioid.

Head-to-head clinical trials comparing different analgesics, separately or in combination, are rare. One example is a small (57 subjects enrolled; 41 trial completers) randomized, double-blind crossover trial in patients with neuropathic pain, which showed that gabapentin and morphine combined achieved better analgesia at lower doses of each drug than either as a single agent (Gilron et al. 2005). On the other hand, the gabapentin–morphine combination resulted in a higher frequency of constipation than gabapentin alone and a higher frequency of dry mouth than morphine alone.

The common decision in clinical practice when optimal pain relief has not been achieved is whether to switch to a new treatment or to add it to what is currently being provided. Given the paucity of combination drug trials, this decision is currently guided by practical considerations. Switching to another monotherapy is often less costly than combining two or more treatments and often is done when a patient has had only a minimal response to and/or poor tolerance of the initial treatment. On the other hand, adding a second treatment may be favored when there has been at least a partial response to the first therapy or when the second treatment has a different mechanism of action that may complement the original treatment. Factors influencing combination therapy decisions include not only added efficacy but also costs, side effects, adherence, and patient preferences. Sometimes, the secondary effects of a drug may influence the decision to use it in a particular patient. For example, the side effect of sedation that occurs with certain medications (e.g., gabapentin or pregabalin) may be troublesome in one patient whereas in another it may be useful to treat comorbid insomnia, particularly if taken at bedtime. Likewise, the antidepressant effects of a particular adjunctive pain medication (e.g., SNRIs like duloxetine or venlafaxine) may reduce both pain and mood disturbances in the patient with diabetic neuropathic pain and comorbid major depression. TCAs could serve the same purpose, although higher doses of TCAs are typically required for antidepressant action than for analgesic action, in which case the side effects of higher-dose TCAs, especially their cardiovascular effects, must be considered as well.

SELECTED PAIN DISORDERS

Neuropathic Pain

Chou et al. (2007a) summarized several key points regarding the prevalence, etiology, and classification of neuropathic pain:

> Neuropathic pain (NP) is often classified by etiology or by the presumed site of neurologic involvement (central or peripheral). More complex classification systems based on symptoms, signs, anatomical distribution, or hypotheses regarding etiologies have been proposed, but it is not clear if such classifications are accurate or reproducible. NP is characterized by continuous or intermittent spontaneous pain, typically characterized by patients as burning, aching, or shooting. Up to 3% of the general population reports NP at some time. NP is most commonly associated with painful diabetic neuropathy, post-herpetic neuralgia (PHN), or lumbar nerve root compression. Diabetic neuropathy occurs in approximately 10% of persons with diabetes. The most common form of diabetic peripheral neuropathy is a distal symmetric polyneuropathy, typically manifested by symptoms beginning in the feet. PHN is defined as pain persisting or recurring at the site of acute herpes zoster 3 or more months after the acute episode. It occurs in up to 25% of patients following an episode of shingles. Symptomatic spinal stenosis and lumbar disc herniation with nerve root compression occur in approximately 3% and 4% of patients with low back pain, respectively. Other causes of NP include cancer-related pain, spinal cord injury, post-stroke pain, HIV-associated neuropathy, and phantom limb pain. Uncommon but potentially debilitating NP conditions include trigeminal neuralgia (incidence 4/100,000 population). In the U.S., health care and disability-related costs associated with NP are estimated at almost $40 billion annually. (Chou et al. 2007a, p. 6)

lamotrigine, topiramate, and valproic acid) and SSRIs. However, such indirect analyses must be interpreted cautiously.

Chou et al. (2007a) also summarized the results of 6 systematic reviews that evaluated the benefits of gabapentin, pregabalin, SNRIs, or topical lidocaine for neuropathic pain. All of the newer medications for neuropathic pain were superior to placebo in at least one systematic review. The systematic reviews included a total of 17 unique placebo-controlled trials of gabapentin, 5 trials of pregabalin, 3 trials of venlafaxine, 6 trials of topical lidocaine, and 2 trials of duloxetine. None of the systematic reviews found any published reports of a head-to-head trial of one of these drugs versus another. Several of the reviews also concluded that TCAs were effective (the best evidence was for amitriptyline), and there were limited data for the effectiveness of SSRIs. It should also be noted that many of the TCA studies performed several decades ago had smaller samples than trials of currently approved drugs. For example, the sum total of patients with diabetic neuropathy studied in all TCA trials was less than 120 (Chong and Hester 2007). Also, a number of the TCA studies used a crossover design rather than a parallel-group design.

Eisenberg et al. (2006) conducted a systematic review of trials evaluating the use of opioids for neuropathic pain. Of 23 trials, 14 were classified as short-term (<24 hours), and 9 as intermediate-term (median, 28 days; range, 8–70 days). The short-term trials had contradictory results. In contrast, all 9 intermediate-term trials demonstrated opioid efficacy: 13 points lower (95% CI = –16 to –9) than placebo on a scale of 1–100.

The European Federation of Neurological Sciences published guidelines on pharmacological treatment of neuropathic pain in 2006 (Attal et al. 2006), which are generally concordant with the Agency for Healthcare Research and Quality evidence-based report. The European Federation of Neurological Sciences concluded that there was level A evidence for the efficacy of TCAs, gabapentin, pregabalin, and opioids in neuropathic pain, followed by topical lidocaine in postherpetic neuralgia and SNRIs in diabetic neuropathy. They also concluded that diabetic and nondiabetic painful polyneuropathies are similar in symptomatology and response to treatment. The only exceptions noted were that HIV- and chemotherapy-induced neuropathy may be more refractory to treatment. The principal opioids studied have been oxycodone and tramadol, both of which have proven superior to placebo. Trials of topical capsaicin have provided discrepant results. The antiarrhythmic drug mexiletine, the *N*-methyl-D-aspartate antagonist memantine, and topical capsaicin have not shown convincing efficacy.

A consensus panel from the IASP likewise concluded that first-line treatments for neuropathic pain include certain antidepressants (i.e., TCAs and SNRIs), calcium channel $\alpha_2\delta$-ligands (i.e., gabapentin and pregabalin), and topical lidocaine (Dworkin et al. 2007). Opioid analgesics and tramadol were recommended as second-line treatments. The IASP also noted: "Although few clinical trials have been conducted, no medications have demonstrated efficacy in patients with lumbosacral radiculopathy, which is probably the most common type of neuropathic pain" (Dworkin et al. 2007, p. 237). Indeed, an RCT evaluating nortriptyline, morphine, and their combination in patients with chronic lumbar root pain found no greater efficacy with the combination than with either medication alone or placebo (Khoromi et al. 2007). The IASP also noted that little is known regarding the treatment response of those with mild to moderate neuropathic pain because most trials have enrolled patients with more severe neuropathic pain, and long-term effectiveness is unknown because most RCTs have been of less than 3 months' duration. The IASP also favored secondary-amine TCAs (nortriptyline and desipramine) over tertiary-amine TCAs (amitriptyline and imipramine) because of their comparable analgesia (Max et al. 1992; Rowbotham et al. 2005; Watson et al. 1998) and fewer side effects. Finally, the IASP concluded that the magnitude of pain reduction associated with opioid analgesics is at least as great as that obtained with other treatments for neuropathic pain.

No clear first choice emerges among FDA-approved drugs for neuropathic pain. The most common adverse events for gabapentin and pregabalin include dizziness, somnolence, and weight gain, and nausea can be a perplexing side effect of SNRIs. Sometimes, a drug may be preferentially chosen because of comorbid conditions (e.g., gabapentin or pregabalin for the patient with neuropathic pain and insomnia, or duloxetine when neuropathic pain is accompanied by major depression). Also, lower doses of two drugs may produce better analgesia with fewer side effects in selected patients (Gilron et al. 2005). Finally, switching or adding medications will frequently be necessary because no more than 40%–60% of patients obtain partial relief from a single agent (Dworkin et al. 2007).

Fibromyalgia

Mechanisms and Evaluation

Fibromyalgia is one of the most common musculoskeletal disorders seen in rheumatology practice as well as primary care. It is often classified among the functional somatic syndromes (FSSs), which include irritable bowel syndrome, chronic fatigue syndrome, temporomandibular joint disorder, interstitial cystitis, and other symptom-based conditions manifested by a cluster of symptoms for which the pathophysiological mechanism is not well understood (Aaron and Buchwald 2001). Patients with one FSS often suffer from one or more other FSSs as well as psychological comorbidity,

including depression, anxiety, and histories of abuse during childhood or as adults. The distinction between FSS and somatoform disorders is also being revisited (Kroenke et al. 2007). However, it does not appear that FSSs are entirely explained by psychological factors (Henningsen et al. 2003), and emerging research also shows biological factors that may be causative or contributory.

The American College of Rheumatology core diagnostic criteria for fibromyalgia are quite simple and do not require any laboratory or radiological testing. They are twofold:

1. Generalized pain that is both widespread (i.e., on both the right and left sides of the body, upper and lower halves, and axial as well as proximal arms and legs) and chronic (lasting ≥3 months)
2. Multiple tender points on physical examination (located in the front and back of the neck, upper chest and back areas, iliosacral and posterior gluteal areas, elbows and knees)

Although the American College of Rheumatology criteria technically require a tender point threshold (≥11 of 18), many clinicians do not actually count tender points but rather establish that the patient is tender at multiple areas, which can be done in 5–10 seconds. Besides multiple tender points, the other diagnostically useful finding is that, unlike patients with arthritic conditions (e.g., osteoarthritis, rheumatoid arthritis, systemic lupus) who mainly suffer from arthralgias (pain and tenderness over the joints or periarticular regions), fibromyalgia patients experience myalgias (pain and tender points in nonarticular regions). In fact, recent research shows that fibromyalgia patients feel tenderness wherever you apply pressure, including areas previously considered to be "control points" (Clauw 2007). The tenderness simply reflects the fibromyalgia patient's tendency toward allodynia (experiencing pain from stimuli that would normally be nonpainful) or hyperalgesia (experiencing more severe pain from stimuli that would normally be only mildly painful). Given that the symptoms seem to arise from disturbances in the central processing of pain and that tender points are a relatively nonspecific finding, some have recently advocated calling the condition *chronic widespread pain.*

The primary problem in fibromyalgia appears to be not that there is too much input coming from the pressure nociceptors peripherally but rather that there is inadequate filtering of that activity, perhaps because of decreased activity of descending anti-nociceptive pathways. In fact, multiple mechanisms seem to be operative in fibromyalgia (Abeles et al. 2007). Two key mechanisms are as follows:

1. Functional imaging studies in fibromyalgia patients have shown increased blood flow to pain-relevant areas of the brain at lower thresholds of nociceptive input.
2. There appears to be dysregulation of descending inhibitory pain pathways. Thus, the pain "amplifier" is turned up, and the "mute" button is turned down in fibromyalgia patients. Collectively, this is known as *central sensitization.*

Not only is fibromyalgia accompanied by psychiatric comorbidity, it also can coexist with other rheumatological disorders. For example, as many as one-quarter of patients with rheumatoid arthritis and other systemic arthritides may also have fibromyalgia. Thus, if an individual with arthritis or another musculoskeletal disorder also has chronic widespread pain, therapies effective for fibromyalgia should be added to the treatment regimen. Also, communication with the patient, including explanations about central sensitization and abnormal pain processing, may be helpful. Despite assumptions that being "labeled" with fibromyalgia may adversely affect patients, it has been shown that patients have had significant improvement in health satisfaction and symptoms after having received this diagnosis (K. P. White et al. 2002).

Pharmacotherapy

Five types of medications are effective in fibromyalgia: 1) TCAs, 2) cyclobenzaprine, 3) tramadol, 4) SNRIs (duloxetine, milnacipran), and 5) $\alpha_2\delta$-ligand anticonvulsants (pregabalin, gabapentin). Although classified as a muscle relaxant, cyclobenzaprine has a chemical structure closely related to that of the TCAs, which may partly account for its effectiveness in fibromyalgia. Although multiple trials have shown the effectiveness of tramadol in fibromyalgia, the few studies of stronger opioids have not established their efficacy. Also, the few studies of NSAIDs in fibromyalgia have also had negative results, suggesting that a class of drugs considered first-line treatment for arthritis and other musculoskeletal disorders may not be effective in treating fibromyalgia.

Perhaps because clinicians are more familiar with traditional analgesics than with medications proven effective in treating fibromyalgia, there is a disconnect between current practice and evidence. This was highlighted by Clauw (2007):

> Market surveys suggest that the no. 1 class of drugs currently used to treat fibromyalgia in the United States is NSAIDs, whereas opioids are no. 3 or 4, even although there is no evidence that either of these classes of drugs works in fibromyalgia. Moreover, most fibromyalgia patients are not being given adequate education about their disease, nor are they given access to

exercise and cognitive-behavioral therapy programs. So it should not be surprising that these patients are frustrated and trying to prove that they really have something wrong with them when they come in to see us. (Clauw 2007, p. 107)

A meta-analysis of antidepressants published in 2000 found 13 trials with evaluable data involving three classes of antidepressants: TCAs (9 trials), SSRIs (3 trials), and *S*-adenosyl-L-methionine (2 trials) (O'Malley et al. 2000). Overall, antidepressants were superior to placebo, with an NNT of 4. The effect sizes for pain, fatigue, sleep, and overall well-being were all moderate (range = 0.39–0.52). In the 5 studies where there was adequate assessment for treatment response independent of depression, only 1 study found a correlation between symptom improvement and depression scores. Antidepressant class did not make a difference, although only 3 trials tested SSRIs. Since this meta-analysis, 2 more trials of SSRIs in fibromyalgia have been published: a flexible-dose trial showing that fluoxetine (mean dosage = 45 mg/day) was superior to placebo in 60 women (Arnold et al. 2002), and an inconclusive trial of citalopram in 40 patients (Anderberg et al. 2000). There is more conclusive evidence for TCAs in treating fibromyalgia than for SSRIs; however, evidence for the superiority of TCAs compared with SSRIs in treating this condition is not as convincing as the evidence for their superiority in treating neuropathic pain.

A meta-analysis of 4 trials found that cyclobenzaprine (10–40 mg/day) was also superior to placebo (Arnold et al. 2000). Again, this is not surprising, given that its structure and pharmacological properties are quite similar to those of the TCAs. Finally, 2 trials—with 100 patients (Russell et al. 2000) and 313 patients (Bennett et al. 2003), respectively—showed that tramadol was superior to placebo in treating fibromyalgia, although the largest trial combined tramadol with acetaminophen.

The most research in terms of pharmacotherapy for fibromyalgia over the past 5 years has involved the SNRI antidepressants and the $\alpha_2\delta$-ligand anticonvulsants (Table 66–5). Pregabalin, duloxetine, and milnacipran have each proven effective in several positive Phase III RCTs (Arnold et al. 2004, 2005, 2007b; Clauw et al. 2007a, 2007b; Crofford et al. 2005; Gendreau et al. 2005; Russell et al. 2008). Pregabalin and duloxetine are the first FDA-approved drugs for the treatment of fibromyalgia, and the makers of milnacipran will be seeking approval. Gabapentin, another $\alpha_2\delta$-ligand, has been evaluated in a single trial, the results of which were positive (Arnold et al. 2007a). Another SNRI, venlafaxine, was tested in a low-dose trial (75 mg/day) and did not differ in efficacy from placebo (Zijlstra et al. 2002). Certainly, the strongest evidence exists for pregabalin, duloxetine, and milnacipran. Pregabalin and duloxetine (as well as milnacipran if FDA approval is obtained) could be considered first-line pharmacotherapies for fibromyalgia, along with TCAs, cyclobenzaprine, and tramadol. Given their longer track record, evidence of efficacy, and low cost, TCAs or cyclobenzaprine might be tried initially, assuming that the patient does not have any contraindications. Tramadol could be a second-line choice, although the fact that it is a weak opioid should be taken into consideration. Generic gabapentin and venlafaxine would be less expensive than the other drugs shown in Table 66–5, although there is only a single trial supporting the use of gabapentin and no positive RCT results for venlafaxine.

TABLE 66–5. Efficacy of SNRI antidepressants and anticonvulsants in fibromyalgia: summary of randomized, placebo-controlled clinical trials

Drug	Study	*N*	Study duration (weeks)	Primary endpoint	Beneficial?
Pregabalin[a]	Crofford et al. 2005	529	8	Mean pain score	Yes
Pregabalin[a]	Arnold et al. 2007c[b]	750	14	Mean pain score	Yes
Duloxetine[a]	Arnold et al. 2004	207	12	Fibromyalgia Impact Questionnaire (total and pain scores)	Yes
Duloxetine[a]	Arnold et al. 2005	354	12	Brief Pain Inventory (average pain severity)	Yes
Duloxetine[a]	Russell et al. 2008	520	26	Brief Pain Inventory (average pain severity) Patient Global-Rated Improvement	Yes
Milnacipran	Gendreau et al. 2005	125	12	Pain intensity (pain diary) Average daily pain score	Yes
Milnacipran	Clauw et al. 2007b[b]	888	24	Composite (pain severity plus global improvement plus physical function)	Yes
Milnacipran	Clauw et al. 2007a[b]	1,196	24	Composite (pain severity plus global improvement)	Yes

Drug	Study	*N*	Study duration (weeks)	Primary endpoint	Beneficial?
Gabapentin	Arnold et al. 2007a	150	12	Brief Pain Inventory (average pain severity)	Yes

Note. SNRI = serotonin–norepinephrine reuptake inhibitor.

[a]Pregabalin and duloxetine are U.S. Food and Drug Administration (FDA)–approved for the treatment of fibromyalgia. It is expected that applications for FDA approval of milnacipran will be submitted in 2009.

[b]Presented in abstract form but not yet published.

In the Phase III trials summarized in Table 66–5, pregabalin dosages were 300–450 mg/day (divided into twice-daily doses), duloxetine dosages were 60–120 mg once a day, and milnacipran dosages were 100–200 mg once a day. In all trials, the difference in efficacy between the highest and lowest dosages of each drug was small to minimal, whereas side-effect rates increased somewhat at higher dosages. Thus, the majority of fibromyalgia patients who respond to these drugs will do so with 300 mg of pregabalin, 60 mg of duloxetine, or 100 mg of milnacipran per day. The most bothersome side effect of duloxetine and of milnacipran (as well as venlafaxine) is nausea, which may be lessened by starting therapy at lower dosages (e.g., duloxetine 30 mg/day or venlafaxine 37.5 mg/day) for the first 1–2 weeks and by taking the drug with food. The most bothersome side effects with pregabalin and gabapentin are somnolence (which often improves with treatment and may be reduced by using low initial doses and having the patient take the only dose or the highest dose at bedtime), dizziness, and weight gain.

Nonpharmacological Treatment

More than with most other pain disorders, nonpharmacological treatment for fibromyalgia is especially important, and few patients should be treated with medication only. Several systematic reviews have shown that the three treatments with the most evidence of efficacy are exercise (particularly aerobic exercise), education about fibromyalgia (either individually or in groups), and CBT (Goldenberg et al. 2004; Henningsen et al. 2007; Sim and Adams 2002; van Koulil et al. 2007). A systematic review of 34 RCTs (involving 2,276 subjects) evaluated exercise in fibromyalgia and found that aerobic-only exercise had moderate positive effects on global well-being (effect size, 0.49), physical function (effect size, 0.66), and pain (effect size, 0.65) (Busch et al. 2007). Strength and flexibility exercises were underevaluated. A review of 8 RCTs of balneotherapy (pool exercise) also showed beneficial results in fibromyalgia (Gowans and deHueck 2007), and this may be an alternative as an initial form of exercise for individuals with arthritis, to reduce weight bearing on arthritic joints, or for patients who fear exercise will exacerbate their pain. Seven RCTs of CBT (2 of which also included exercise) involving a total of 595 patients showed benefits for CBT in 5 of the 7 trials (van Koulil et al. 2007). Education about fibromyalgia has been studied in numerous trials, both individually and coupled with one or more other interventions, and appears to have a positive effect (Goldenberg et al. 2004; Sim and Adams 2002). Education coupled with exercise seems a particularly valuable bundled intervention (Burckhardt 2006; Karjalainen et al. 2000; Rooks et al. 2007). Educational and self-management resources are readily available online from organizations like the National Fibromyalgia Association, the American College of Rheumatology, and the Arthritis Foundation. Finally, there are insufficient data to recommend acupuncture, chiropractic therapy, massage therapy, trigger point injections, or other nonpharmacological or CAM treatments for fibromyalgia (Goldenberg et al. 2004; Henningsen et al. 2007; Mayhew and Ernst 2007; Sim and Adams 2002; Tan et al. 2007).

Low Back Pain

A series of systematic reviews by Chou and colleagues (Chou and Huffman 2007a, 2007b; Chou et al. 2007b) provides a comprehensive update on the evaluation and management of low back pain. The authors describe the burden of back pain:

> Low back pain is the fifth most common reason for all physician office visits in the U.S. and the second most common symptomatic reason. Approximately one quarter of U.S. adults reported having low back pain lasting at least 1 whole day in the past 3 months, and 7.6% reported at least 1 episode of severe acute low back pain within a 1-year period. Low back pain is also very costly: Total incremental direct health care costs attributable to low back pain in the U.S. were estimated at $26.3 billion in 1998. In addition, indirect costs related to days lost from work are substantial, with approximately 2% of the U.S. work force compensated for back injuries each year. (Chou et al. 2007b, p. 478)

The authors go on to describe several other key points relevant to the clinical epidemiology of low back pain. Most low back pain (85%) is nonspecific—that is, it cannot be attributed to a specific disease or spinal abnormality. Classification schemes frequently conflict with one another, and there is little evidence that labeling patients by using specific anatomical diagnoses improves outcomes. In a primary care setting, low back pain is only occasionally caused by a specific serious disorder, such as cancer (0.7% of cases), compression fracture (4%), or spinal infection

(0.01%). The estimated prevalence of ankylosing spondylitis in primary care patients ranges from 0.3% to 5%. Spinal stenosis and symptomatic herniated disc are present in about 3% and 4% of patients, respectively. The cauda equina syndrome, due to massive midline disc herniation, is very rare (occurring in 0.04% of patients with low back pain). Urinary retention is 90% sensitive, and the probability of the cauda equina syndrome in back pain patients without urinary retention is approximately 1 in 10,000. The probability of cancer in patients presenting with back pain increases from approximately 0.7% to 9% in patients with a history of cancer (not including nonmelanoma skin cancer). In patients with any one of three other risk factors (unexplained weight loss, failure to improve after 1 month, and age >50 years), the likelihood of cancer only increases to approximately 1.2%.

Table 66–6 outlines some key recommendations with respect to the evaluation and management of low back pain. In the absence of red flags, a conservative approach for at least 4 weeks is usually warranted, even if sciatica is present. Magnetic resonance imaging is the preferred imaging procedure but can be reserved for the minority of patients with red flags or persistent symptoms, especially neurological findings. The two most common indications for surgery are herniated disc with persistent symptoms (especially radiculopathy) and spinal stenosis, which together account for less than 10% of cases of chronic back pain. Recent trial data suggest that surgery may be only marginally beneficial for pain due to a herniated disc but more helpful for spinal stenosis (Weinstein et al. 2006, 2008). Psychological factors are stronger predictors of low back pain treatment outcomes than either physical examination findings or the severity or duration of pain. Psychosocial factors that may predict poorer low back pain outcomes include presence of depression, passive coping strategies, job dissatisfaction, higher disability levels, disputed compensation claims, and somatization.

TABLE 66–6. Key aspects of evaluation and management of low back pain

Most back pain (>70%–80%) improves in the first 2–6 weeks. Thus, a 4-week wait (i.e., a conservative approach) is warranted (even with sciatica) in the absence of red flags.

Red flags that may prompt earlier diagnostic testing or referral include the following:

Cancer: history of cancer (strong predictor) or unexplained weight loss, failure to improve after 4 weeks, and age greater than 50 years (all weaker predictors)

Infection (vertebral): fever, intravenous drug use, recent infection (none well studied)

Compression fracture: older age, osteoporosis, steroid use

Treatment: No treatment for back pain has good-quality (grade A) evidence of substantial benefit. The following have fair-quality (grade B) evidence of moderate benefit or small benefits but no significant harm, costs, or burdens:

Pharmacotherapy: acetaminophen, NSAIDs, TCAs, tramadol/opiates, benzodiazepines

Nonpharmacological: chiropractic, acupuncture, massage, yoga, exercise, progressive relaxation, cognitive-behavioral therapy, intensive interdisciplinary rehabilitation

Note. ESR = erythrocyte sedimentation rate; MRI = magnetic resonance imaging; NSAIDs = nonsteroidal anti-inflammatory drugs; TCAs = tricyclic antidepressants.

Medications are the most frequently recommended intervention for low back pain. The most commonly prescribed medications for low back pain are NSAIDs, skeletal muscle relaxants, and opioid analgesics (Chou and Huffman 2007a). Benzodiazepines, systemic corticosteroids, antidepressant medications, and antiepileptic drugs are also prescribed. Frequently used over-the-counter medications include acetaminophen, aspirin, and certain NSAIDs. No treatments for back pain have grade A evidence supporting their use—that is, good-quality evidence of substantial benefits. Table 66–6 summarizes treatments with grade B evidence. For pharmacotherapy, this includes acetaminophen, NSAIDs, tramadol, and TCAs. For all medications, the evidence of beneficial effects on functional outcomes is limited. Skeletal muscle relaxants, which may be beneficial for acute back pain, do not have established efficacy for chronic pain. Although systematic reviews of opioids for various chronic pain conditions have shown moderate benefits, the evidence for opioids specifically for low back pain is sparse and inconclusive (Martell et al. 2007). A recent prospective study found that early prescription of opioids for acute occupational low back injury was associated with an increased risk of work disability at 1 year, even after adjustment for severity of pain, function, and initial injury (Franklin et al. 2008). A systematic review of 25 trials involving 2,206 patients found no benefits for either continuous or intermittent traction in the treatment of low back pain (Clarke et al. 2007). There is also good evidence that systemic corticosteroids are ineffective for low back pain with or without sciatica. One systematic review identified only 7 trials evaluating medications for sciatica (Vroomen et al. 2000). Two small trials suggest that gabapentin may be useful in the subset of patients with radiculopathy.

Ten trials were included in two systematic reviews of antidepressants (Salerno et al. 2002; Staiger et al. 2003). In all of the trials, the duration of therapy ranged from 4 to 8 weeks. Antidepressants were consistently superior to placebo for pain relief, whereas the benefits in terms of functional outcomes were uncertain. The pooled effect size for pain relief was moderate (0.41). Indirect comparisons suggested modest benefits with TCAs but not with paroxetine or trazodone. A recent review did not identify any relevant trials in back pain for SNRI antidepressants such as duloxetine or venlafaxine (Chou and Huffman 2007a).

Osteoarthritis

Osteoarthritis is one of the most common musculoskeletal pain disorders (along with low back pain and fibromyalgia) in both primary care and specialty settings. It typically increases with age (particularly after age 50), with the majority of individuals older than 65 years having at least one joint affected by osteoarthritis. Common joints involve the distal and proximal interphalangeal (but not metacarpal) joints of the fingers, the base of the thumb, the knees, the hips, and the cervical and lumbar regions of the spine. The shoulder and elbow are rarely involved. The most common finding on physical examination is an increase in joint size secondary to osteophyte formation. Plain radiographs are typically the only diagnostic test required to confirm the diagnosis of osteoarthritis, which is manifested by loss of joint space and/or osteophyte formation.

Unlike in rheumatoid arthritis and other inflammatory types of arthritis, the structural changes in osteoarthritis are not amenable to specific disease-modifying treatments. Thus, the focus of treatment in osteoarthritis is reduction of pain and preservation of function. Acetaminophen and NSAIDs, which are inexpensive and available without a prescription, are the mainstays of pharmacotherapy. A systematic review of 13 trials in patients with osteoarthritis of the knee found that both aerobic exercise and home-based quadriceps-strengthening exercise reduced pain (effect size, 0.52 and 0.39, respectively) and disability (effect size, 0.46 and 0.32) (Roddy et al. 2005). Benefits of aerobic and strengthening exercises in osteoarthritis patients were confirmed in a second systematic review (Brosseau et al. 2003). For advanced disease with progressive pain and functional impairment, total hip arthroplasty and knee arthroplasty are effective. In contrast, a systematic review of 23 studies found inconclusive evidence for the benefits of arthroscopic lavage and/or debridement in knee osteoarthritis (Samson et al. 2007). Glucosamine, chondroitin, and intra-articular hyaluronic acid have been the most popular CAM treatments for osteoarthritis, but 4 systematic reviews as well as an overall review (Table 66–7) found that the evidence regarding the efficacy of each of these three treatments is still inconclusive (Arrich et al. 2005; Distler and Anguelouch 2006; Reichenbach et al. 2007; Samson et al. 2007; Vlad et al. 2007).

TABLE 66–7. Glucosamine, chondroitin, and hyaluronic acid for osteoarthritis (OA): summary of systematic reviews

Treatment	Study	Condition	Review type	Benefits	Strength of evidence	Comments
Glucosamine	Vlad et al. 2007	Knee or Hip OA	Meta-analysis (15 trials, 2,825 patients)	Not known	Moderate	Glucosamine hydrochloride (three trials) did not have a significant effect size (0.06), but glucosamine sulfate (12 trials) did (0.44). However, large heterogeneity among trials made conclusions about efficacy uncertain.
Chondroitin	Reichenbach et al. 2007	Knee or Hip OA	Meta-analysis (20 trials, 3,846 patients)	No	Moderate	Minimal to no effect on symptoms. Only three large high-quality trials, which accounted for 40% of patients.
Glucosamine and/or chondroitin	Distler and Anguelouch 2006	Knee or Hip OA	Review of prior reviews	No	Moderate	Review of four prior meta-analyses and large GAIT trial concluded that neither glucosamine nor chondroitin is effective in OA.
Glucosamine and/or chondroitin	Samson et al. 2007	Knee OA	Systematic (21 trials)	Not known	Moderate	Evidence from small trials inconclusive. The GAIT study in 1,583 patients showed no difference from placebo.
Hyaluronic acid (intra-articular)	Arrich et al. 2005	Knee OA	Meta-analysis (22 trials)	No	Moderate	Small but clinically insignificant effect on pain. Only four high-quality trials.
Hyaluronic acid (intra-articular)	Samson et al. 2007	Knee OA	Systematic (42 trials)	Not known	Moderate	Generally some modest benefits compared with placebo but unclear clinical significance.

Note. GAIT = Glucosamine–Chondroitin Arthritis Intervention Trial.

Avouac et al. (2007) conducted a meta-analysis of trials evaluating opioid therapy in osteoarthritis patients. Of the 18 placebo-controlled trials, 13 assessed pain intensity for 2,438 participants receiving opioids and 1,295 receiving placebo. Six studies evaluated stronger opioids (oxycodone in 4 studies, fentanyl and morphine in 1 study each) and 7 studies examined weaker opioids (tramadol in 4 studies, tramadol–acetaminophen combination in 2 studies, and codeine in 1 study). The median trial duration was 12 weeks. The pooled effect size for pain intensity was moderate, at –0.79 (95% CI = –0.98 to –0.59). Sensitivity analysis showed no changes in the conclusions by type of opioid studied, type of scale used to assess pain, or methodological quality of the study. Physical function was assessed in 5 trials, with 1,429 participants receiving opioids (tramadol–acetaminophen in 2 studies; morphine, tramadol, and codeine in 1 study each) and 595 receiving placebo. The median trial duration was 4 weeks. The pooled effect size for physical function was small, at –0.31 (95% CI = –0.39 to –0.24). Again, sensitivity analyses did not change the conclusions. The average treatment discontinuation rate for toxicity was 25% in the opioid group (31% for strong opioids and 19% for weak opioids) versus 7% in the placebo group.

Unlike the many trials of antidepressants for neuropathic pain, fibromyalgia, and chronic low back pain, antidepressants have not been well studied as a treatment for the pain of osteoarthritis. However, recent studies have

treatments less effective. Anxiety may have a similar effect, although the research in this area is less substantial than for depression.

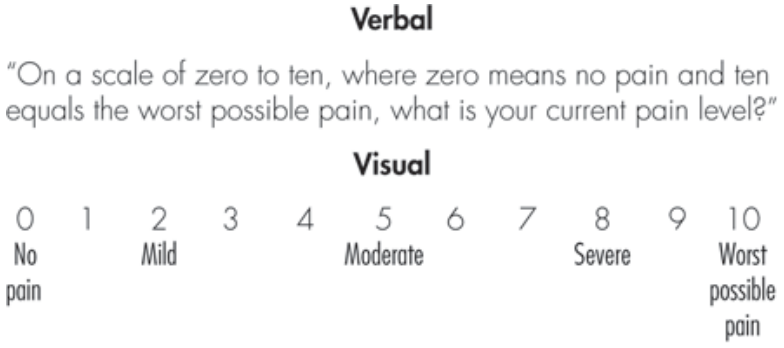
Several trials have shown that depression treatment also benefits patients in pain outcomes, although the effect size for pain is only about half that for depression (Bair et al. 2008; Greco et al. 2004; E. H. Lin et al. 2003). Until more trials are conducted in those with depression and comorbid pain, several suggestions may be considered. First, pain should be asked about when treating depressed or anxious patients, particularly in those who are not achieving remission or optimal responses. Likewise, psychiatric screening should be considered in patients with persistent pain, possibly with brief measures that screen for both depression and anxiety (Kroenke et al., in press). Second, it may be that antidepressant selection is important when pain is a major problem. For some types of pain conditions, TCAs and SNRI antidepressants appear to be more effective than SSRI or other antidepressants, although head-to-head trials are still few. Third, adding CBT, PSM (pain self-management) programs, or other nonpharmacological treatments proven effective for pain could be considered. Fourth, optimizing analgesic management in patients with depression and pain, rather than simply focusing on depression medications, may be important. Increasingly, we may need to consider pain and depression as dual diagnoses, where attention to both is necessary to optimize patients' outcomes.

Placebo Effect

As with other symptom-based conditions (e.g., depression, anxiety, somatoform disorders), pain has a placebo response in the 30%–40% range or higher. This can make it challenging to separate the specific effects of a pain treatment—medication or nonpharmacological—from placebo or other nonspecific effects. Furthermore, it means that the more successful a trial is in masking the patient to active versus control treatment (typically greatest in a placebo-controlled drug trial), the lower the estimated differences from placebo are likely to be. In contrast, less effective masking (e.g., attention–placebo control groups for psychotherapy or behavioral interventions, sham procedures for acupuncture or chiropractic manipulation) or nonexistent masking (e.g., wait-list or treatment-as-usual control groups) are more likely to overestimate the effect of a pain treatment.

At the same time, the role of placebo effects on pain outcomes can be useful in clinical practice, including patient expectancy for an analgesic outcome and the clinical benefits of a positive therapeutic relationship. Pain is the most frequent reason for seeking CAM care (Astin 1998). Although evidence for several CAM treatments may still be lacking, their placebo effects coupled with frustration among many allopathic physicians and patients in the context of chronic pain may account for the popularity of CAM treatments for pain.

Experimental work has also revealed some interesting physiological effects of placebo. A meta-analysis of 12 studies (1,183 participants) was conducted to examine the effects of placebo and an opioid antagonist, naloxone, on pain (Sauro and Greenberg 2005). Placebo administration was associated with a decrease in self-reported pain, and a hidden or blind injection of naloxone reversed placebo-induced analgesia. A recent experimental study in 20 healthy subjects found that the placebo and nocebo effects (i.e., the therapeutic and adverse effects, respectively, of inert substances or sham procedures) are associated with opposite responses of dopaminergic and endogenous opioid neurotransmission in a distributed network of regions throughout the brain (Scott et al. 2008). The results support other literature showing that the belief in and expectation of analgesia induce discrete physiological changes, leading to relief from pain, and this response may be mediated by endogenous opioids.



Assessment and Monitoring of Pain

Clinical trials have often used a wide variety of pain measures in assessing outcomes, and until recently, consensus has been lacking on a standard or optimal approach. This is not unlike other psychiatric disorders or symptom-based conditions where patient-reported measures are necessary to assess clinical outcomes, in contrast to disorders where a universally agreed-on physical measure (e.g., blood pressure) or laboratory test (e.g., for serum cholesterol levels) is the criterion standard. In a review of pain clinical trials published in seven top-tier medical journals in 2003, a total of 50 studies used 28 types of pain assessments (Litcher-Kelly et al. 2007). The most frequently used assessments were a single-item visual analog scale and a single-item 0–10 numeric rating scale (NRS); multidimensional inventories were used infrequently.

Inadequate pain assessment has been identified as a key barrier to appropriate pain management. Important initiatives have aimed to increase awareness of pain as a clinical problem by promoting better pain assessment. The U.S. Department of Veterans Affairs (VA) campaign promoting "pain as the fifth vital sign" requires all VA facilities to assess patients using an NRS of 0–10 for current pain. Even more far-reaching, the Joint Commission on Accreditation of Healthcare Organizations (2000) pain assessment and management standards, implemented in 2001, require accredited health care facilities to assess all patients for pain in both inpatient and ambulatory care settings. Although Joint Commission standards do not mandate a specific method of pain assessment, many organizations have responded by adopting use of an NRS of pain as the "fifth vital sign" (Dahl 2002). A verbal (interviewer-administered)

and visual (self-rated) version of this single-item NRS for pain assessment is shown in Figure 66–2. As a result, assessment of current pain intensity with a single-item rating scale has become nearly ubiquitous in many U.S. health care settings. However, this movement has not led to clear improvements in the quality or outcomes of chronic pain management, and studies have shown that the NRS may not be the optimal measure for assessing and monitoring chronic pain in clinical practice (Krebs et al. 2007; Mularski et al. 2006). An important limitation of single-item pain measurement is that it provides an overly simplified picture of a complex subjective experience.

FIGURE 66–2. Pain numeric rating scale (NRS).

Verbal
"On a scale of zero to ten, where zero means no pain and ten equals the worst possible pain, what is your current pain level?"
Visual
0 1 2 3 4 5 6 7 8 9 10
No pain
Mild
Moderate
Severe
Worst possible pain

Interviewer-administered (verbal) and self-administered (visual) versions of the single-item NRS for pain, also referred to "the fifth vital sign."

Recent consensus recommendations from the Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT) recommend four core chronic pain outcome domains for monitoring treatment response: pain intensity (i.e., severity), physical functioning (i.e., pain-specific disability), emotional functioning (largely depression), and patient-rated overall improvement (Dworkin et al. 2008). The first two domains are captured in the recently validated PEG pain scale based on three items from the Brief Pain Inventory (average pain severity, interference with enjoyment of life, and interference with general activities), shown in Figure 66–3 (Krebs et al. 2008a). For emotional functioning, a clinical or patient-rated assessment of depression is recommended. For overall improvement, the single-item Patient Global Impression of Change scale uses a seven-point rating scale with the options "very much improved," "much improved," "minimally improved," "no change," "minimally worse," "much worse," and "very much worse."

FIGURE 66–3. PEG three-item pain scale.

1. What number best describes your pain on average in the past week?

0	1	2	3	4	5	6	7	8	9	10
No pain	|	|	|	|	|	|	|	|	|	|	Pain as bad as you can imagine

2. What number best describes how, during the past week, pain has interfered with your general activity?

0	1	2	3	4	5	6	7	8	9	10
Does not interfere	|	|	|	|	|	|	|	|	|	|	Completely interferes

3. What number best describes how, during the past week, pain has interfered with your enjoyment of life?

0	1	2	3	4	5	6	7	8	9	10
Does not interfere	|	|	|	|	|	|	|	|	|	|	Completely interferes

The competing demands of clinical practice in which visits are short and pain is often a secondary focus make efficiency as well as validity of assessment a paramount concern. At the same time, there must be a balance between number of items and key operating characteristics such as reliability, validity, and responsiveness to therapy. For example, "ultrabrief" depression measures containing two or three items perform better than single-item depression measures (Mitchell and Coyne 2007). In this sense, the three-item PEG may be preferable to the single item NRS, which is currently promulgated by various accrediting bodies but which has substantial limitations, as demonstrated in two recent studies (Krebs et al. 2007; Mularski et al. 2006). Moreover, the PEG captures both the severity and the functional interference dimensions of pain, whereas the NRS captures only pain severity. This is essential in pain management because pain interference has been shown to have an even greater impact than simple severity on quality of life and other patient-centered outcomes (Von Korff et al. 1992).

Economic Issues

As mentioned in the introduction to this chapter, pain costs the United States more than $100 billion each year in health care and lost productivity (Stewart et al. 2003), and pain medications are the second most prescribed class of drugs (Turk 2002). Despite the importance of considering drug costs, a recent review of 142 chronic pain–related economic evaluations published between 1988 and 2006 found important methodological shortcomings (Vetter 2007). Only a few studies combined the economic analysis along with an RCT, the economic endpoints had limited time horizons, and there was a failure to address the protracted costs versus benefits of treating long-term and often recurrent chronic pain conditions. Unlike many cardiology and oncology trial–based economic evaluations with societal perspectives and protracted time horizons (e.g., longer-term survival or death), many of the economic analyses related to chronic pain treatment have been restricted to a third-party insurer perspective and have used a limited time horizon of less than 1 year. For example, it is possible that a more expensive medication may be more cost-effective than a lower-cost medication if it were shown that time lost from work was less or enhancements in quality in life were greater. In an economic evaluation of controlled-release oxycodone compared with oxycodone–acetaminophen for osteoarthritis, the more costly controlled-release medication proved more effective and less costly from a societal perspective, including greater gains in quality-adjusted life years and lower costs associated with time lost from work or other activities (Marshall et al. 2006). In a similar evaluation of pregabalin versus gabapentin for neuropathic pain, the authors concluded that pregabalin was more cost-effective, costing about $15 for each additional day with no pain or only mild pain and about $600 for each additional patient with no pain or mild pain (Rodríguez et al. 2007). Both studies used simulated analyses from existing trial data rather than head-to-head

comparisons in an RCT, so the conclusions must be interpreted with caution. Nonetheless, pharmacoeconomic decision making needs to incorporate not only drug costs but also differential efficacy and side effects, impacts on work and quality of life, and the adjudication of patient, insurer, employer, and societal perspectives.

Gaps in Knowledge Base Regarding Treatment of Chronic Pain

There are several important gaps in our knowledge regarding treatment that in fact are probably not unique to chronic pain. First, there is a paucity of head-to-head trials, meaning that although we can draw conclusions about the effectiveness of a particular monotherapy compared with a placebo or minimal treatment, we have much less information about the comparative effectiveness of different treatments. Second, few trials have evaluated different strategies for choosing initial treatment, so that deciding between first-line and subsequent treatments is more a matter of expert consensus, clinician experience, and patient preferences. Third, evidence is sparse on the effectiveness of dual-medication or other combination therapy versus monotherapy or sequential treatment, even though patients are frequently prescribed more than one medication or treatment. Fourth, most treatment trials have been short-term, so evidence of benefits sustained beyond 4–12 weeks is often lacking; this is a critical gap given the fact that our focus is on the management of chronic pain.

Despite these gaps, substantial evidence has accumulated over the past several decades about what works and what does not work for treating chronic pain. Avoiding ineffective treatments and maximizing the use of treatments proven beneficial in clinical trials are likely to produce better outcomes than have often been experienced by clinicians and patients in the management of chronic pain.

Chapter 67. Ethical Considerations in Psychopharmacological Treatment and Research

ETHICAL CONSIDERATIONS IN PSYCHOPHARMACOLOGICAL TREATMENT AND RESEARCH: INTRODUCTION

The discovery of chlorpromazine's effectiveness in treating symptoms of schizophrenia in 1952 (Delay and Deniker 1952) launched the modern era of pharmacological treatment of psychiatric disease and was a critical development in the compassionate care of people living with mental illness and in the reduction of the societal burden of mental disease. Chlorpromazine's introduction was followed in 1958 by the introduction of imipramine as a treatment for depression (Kuhn 1958) and in 1960 by that of chlordiazepoxide for anxiety (Shorter 1997). Within years, these medications eased the symptoms of hundreds of thousands of the most severely and persistently ill individuals—many of whom otherwise would have endured a lifetime of suffering, disability, and institutionalization, as had millions before them.

As the ensuing decades have shown, the use of psychotropic medications has deep ethical as well as clinical and social implications. This is because psychopharmacological agents have the power not only to relieve severe mental illness symptoms but also to profoundly influence an individual's most fundamental personal attributes—for example, the abilities to experience emotions fully, to relate to others in an empathic and loving way, to engage in focused and sustained thought, to understand oneself more completely, and to extinguish maladaptive or hurtful impulsive behaviors. Taking a selective serotonin reuptake inhibitor may cause a chronically depressed person to experience herself for the first time as relaxed and outgoing. A highly distractible child who is prescribed a psychostimulant may suddenly perceive himself to be smart and likeable. The ability of psychotropic agents to influence personality, mood, cognitions, and psyche raises a number of questions about their ethical use. For example, under what circumstances is it acceptable to use sedating or antipsychotic medications coercively to prevent severely mentally ill individuals from harming themselves or others? When, if ever, is it acceptable to use psychotropic medications for enhancement of personality or intellectual performance—that is, to help psychiatrically healthy persons to become "better than well" (Kramer 1993)?

As psychopharmacology becomes more innovative, extending further into relatively uncharted territory such as the treatment of cognitive dysfunction and substance abuse, we will be challenged by an expanding number of ethical questions regarding treatment selection, the process of informed consent, and related issues (Roberts 2002c; Roberts and Dyer 2004). Furthermore, the acceleration in pharmacological research involving mentally ill adults and children provokes its own set of ethical concerns (Hoop et al. 2008; Roberts and Krystal 2003). The nature of psychiatric illness itself can pose barriers to informed consent for research participation, and protocol features such as placebo control groups and symptom provocation may expose individual research participants to risks that are difficult to understand prospectively and may be significant (Roberts and Roberts 1999). Investigators must continue to address these issues in an explicit, thoughtful manner to maintain the public's trust.

For all these reasons, excellence in psychopharmacology requires sensitivity to a growing range of

ethical considerations. The aim of this chapter is to introduce the reader to these issues and to provide a framework for analyzing them. We begin with a discussion of why ethical psychopharmacology is vital to maintaining public trust in psychiatry, and we describe essential ethics skills for psychopharmacologists. We then discuss a number of ethical concerns and controversies in psychopharmacology. The topics covered are not exhaustive but were selected to give the reader a sense of the scope of issues in this important field. We finish by addressing one of psychiatry's most pressing concerns: the need to anticipate and manage the ethical issues that arise in relation to overlapping roles and potential conflicts of interest in interactions with industry.

ETHICS, PSYCHOPHARMACOLOGY, AND THE PUBLIC TRUST

Clear standards of ethics and professional behavior help preserve public trust in psychiatry (Roberts and Dyer 2004). Consequently, as the practice of psychiatry has become increasingly devoted to delivering biologically based treatments, creating ethical standards for psychopharmacological interventions has become a matter of growing importance (Ghaemi 2006). The ethics of psychopharmacology is relatively uncharted territory, however, compared with our detailed understanding of other ethical aspects of clinical psychiatry, including boundary issues in psychotherapy and psychoanalysis, the appropriate use of power in involuntary treatment, and the duty to warn third parties about treatments' potential harm (Dyer 1988; Gabbard 1999; Levine 1972; Roberts and Dyer 2004). The ethical issues involved in clinical psychopharmacology have received relatively little attention in the psychiatric literature, with a handful of important exceptions (Brown and Pantelis 1999; Tasman et al. 2000). A major current goal of our profession is to clearly articulate whether, and if so, precisely how, the psychopharmacologist's ethical obligations differ from those of the psychoanalyst, the forensic specialist, or the emergency psychiatrist.

Clarity about the ethical duties of the psychopharmacologist is needed in part because psychiatrists practice in the context of an enduring public debate about the medical model of mental illness and its biological treatments (Szasz 1960). Some of this controversy can be attributed to a Calvinistic view of psychological suffering as an integral aspect of the human condition rather than as a symptom of disease (Kramer 1993; Sperry and Prosen 1998). Individuals and groups who reject the medical view of mental illness may perceive psychopharmacology as inappropriate attempt to avoid suffering rather than enduring or learning from it. Even those who are generally supportive of psychiatric care may feel that Americans have become too reliant on psychotropic medications as "quick fixes" for their problems. Within the psychiatric community, the increased prescribing of these drugs over the past several decades (Wong et al. 2004) is generally attributed to better recognition of psychopathology and the introduction of safer and more efficacious medications (Arehart-Treichel 2004). Among psychiatry's critics, however, increased prescribing may be interpreted as the overuse of drugs to treat social or moral problems or to perform "cosmetic pharmacology"—that is, to use medication to enhance normal functioning rather than to treat illness (Bjorklund 2005; Elliott 2003; Kramer 1993).

Public trust in psychiatry may also be affected by negative or inaccurate perceptions of psychopharmacology. On the one hand, a psychotropic medication may be viewed, for instance, as more harmful than the underlying condition or than other treatment approaches, such as psychotherapy. Medications may indeed be more likely to cause side effects, more stigmatizing (i.e., apparently indicating more severe pathology), and more easily misused (Bjorklund 2005; Elliott 2003; McHenry 2005; Sperry and Prosen 1998). On the other hand, the marketing of over-the-counter medications with psychotropic properties may suggest that these medications are relatively mild or benign when they may in fact have very potent but poorly understood effects (Beaubrun and Gray 2000; Werneke 2006). Medications for mental disorders may also be perceived as less "scientific" than treatments for other diseases (McHenry 2005), because relatively little is known about the mechanism of action of many psychiatric medications.

Public trust is also affected by the activities of the pharmaceutical industry (McHenry 2006). Direct-

to-consumer advertising to encourage individuals to seek treatment for depression, social anxiety disorder, attention-deficit/hyperactivity disorder, and other conditions can be justified ethically by its ability to increase public awareness and perhaps decrease social stigma. Still, this form of advertising may also leave some observers with the impression that psychiatric diagnosis and treatment are linked to the sale of pharmaceuticals (Bjorklund 2005; Elliott 2003; Halasz 2004).

Conflicts of interest or the appearance of conflicts of interest among psychiatrists with ties to pharmaceutical companies have therefore become a major concern (Carlat 2007; Harris and Roberts 2007; Moncrieff et al. 2005). Many educational activities in psychiatry have been funded by the pharmaceutical industry, from large symposia at meetings of professional societies to one-on-one "detailing" by pharmaceutical representatives who meet with psychiatrists and residents in clinic offices (Carlat 2007; Hill 2006; Lurie et al. 2005; Wazana 2000). Although many physicians do not believe that such encounters affect their prescribing practices, empirical evidence suggests that these interactions are more influential than has been realized or acknowledged (Orlowski and Wateska 1992; Wazana 2000). The pharmaceutical industry also funds a significant proportion of treatment research in psychiatry, a phenomenon that has been criticized by some for resulting in a biased evidence base regarding pharmaceuticals (Melander et al. 2003). Finally, industry provides direct payments to many psychiatrists for educational, clinical, or research activities—for example, via fees for giving presentations, attending industry-sponsored activities, referring patients to research studies, or conducting clinical trials.

Arrangements such as these create potential conflicts of interest (Roberts and Dyer 2004). While such conflicts occur naturally throughout all of medicine, they may lead to ethical lapses and/or create an appearance of unethical behavior that endangers the public trust. Clinicians and clinical scientists are experts, patient care advocates, and organizational resources to society, and it is logical that they would be the individuals who would be approached by industry to assume overlapping roles related to their knowledge and various professional efforts. The roles themselves are not inherently or necessarily unethical. However, certain activities may be fundamentally incompatible with the professional obligations of being a physician—for example, appearing in advertisements for unproven treatments (American Medical Association Council on Ethical and Judicial Affairs 2002). Furthermore, the multiplicity of roles and competing obligations of the various roles, taken together, may in fact adversely affect a clinician's or clinician-scientist's decisions in small and large ways. Finally, the perception of conflict of interest may raise public concerns that undermine the integrity of the profession (Harris 2007; Harris and Roberts 2007). Managing potential conflicts and overlapping roles requires careful attention to issues such as disclosing potential conflicts of interest and establishing safeguards for patients and research participants, approaches that are discussed in detail at the end of this chapter (see "Management of Overlapping Roles and Conflicts of Interest in Psychopharmacology").

All of these factors highlight the importance of establishing clear and consistent standards for ethical psychopharmacology to maintain the trust in the profession's ability to diagnose and treat mental disorders in an unbiased and scientifically sound manner. This is especially important today, while the evidence base for psychiatric treatments is modest and potentially controversial practices such as off-label prescribing are unavoidable if we are to provide treatment for certain understudied disorders and populations (Gazarian et al. 2006; Miskimen et al. 2003). Without the confidence of the public, funding for much-needed research may suffer and the stigma of mental illness may deepen, making it even more difficult for individuals in need to seek, obtain, and adhere to psychopharmacological treatments.

ESSENTIAL ETHICS SKILLS OF PSYCHOPHARMACOLOGISTS

In contrast to the view that ethics and professionalism cannot be taught and learned, we believe that ethical behavior, like clinical acumen, is based on a set of skills that are learned and honed over time

(Roberts and Dyer 2004; Roberts et al. 1996). Six key ethics skills are crucial to psychiatric practice, as discussed below, and all are directly relevant to clinical psychopharmacology and psychopharmacological research (Table 67–1).

1. The first essential ethics skill is ethical sensitivity, the ability to detect ethical issues when they arise. To recognize ethical issues requires an awareness of the meaning of bioethics concepts such as autonomy, beneficence, and justice (Table 67–2) and an understanding of the dilemmas that occur when these principles are in conflict (Table 67–3). As a simple example, the psychiatrist who evaluates a pregnant woman with bipolar disorder should recognize that the selection of treatment has an ethical dimension, because of the possibility of teratogenicity, which requires careful consideration along with the clinical indications.
2. A second related skill is the ability to anticipate that ethical conflicts are likely to arise in certain situations. In the clinical sphere, such situations include involuntary treatment, which may pit a clinicians' duty to respect autonomy against the duty to act with beneficence. In research, ethically higher-risk situations include protocols that involve medication washout periods or placebo groups, which in the absence of adequate safeguards may pose harm for some research participants.
3. The third essential ethics skill is the psychopharmacologist's ability to monitor how his or her own moral beliefs and values may affect ethically important thinking and decision making. For instance, a psychiatrist who has been personally devastated by the suicide of a patient may recognize that this experience has made him or her more driven to "do good" for patients via aggressive pharmacotherapy and less capable of respecting the decisionally capable patient's right to refuse treatment. Similarly, a researcher whose spiritual beliefs include a high value on social justice may realize that this influences his or her thinking about subject recruitment and that it is helpful to discuss this aspect of protocol design with collaborators who do not share the same values.
4. A fourth key ethics skill is the ability to recognize and respect one's professional limits. Our appropriate sphere of professional activity is properly bounded by the extent of our education, training, and experience and by the relative availability of more qualified colleagues. Some psychopharmacologists may not have the training or experience to conduct combined medication management/psychodynamic psychotherapy, whereas others may lack qualifications to treat psychiatrically ill patients during childhood, pregnancy, or old age or those with concomitant medical illness. Physicians who practice in remote or isolated communities may ethically provide a broader range of services than those who practice in large urban centers with many subspecialists. No one person is able to provide every kind of medical or psychiatric evaluation and treatment; referring patients demonstrates humility and self-awareness as well as dedication to the principles of nonmaleficence and beneficence.
5. A fifth skill is the willingness to seek and use ethics consultations or guidelines in appropriate situations. Clinicians who are faced with ethical challenges have many resources to guide them, including written ethics standards, codes, and guidelines. All psychopharmacologists should be familiar with ethics resource documents of the American Psychiatric Association, such as *The Principles of Medical Ethics With Annotations Especially Applicable to Psychiatry* (American Psychiatric Association 2001; available online at http://www.psych.org/MainMenu/PsychiatricPractice/Ethics/ResourcesStandards/PrinciplesofMedicalEthics.aspx), and of the American Medical Association Council on Ethical and Judicial Affairs (2002). In addition, many hospitals and academic centers have ethics committee members or ethics consultants who can be contacted for help in defining an ethical problem and identifying a range of acceptable solutions. Researchers can seek guidance from the relevant institutional review board, through a formal protocol review and/or informal consultation.
6. The final essential skill for psychiatrists is the ability to create ethical safeguards to anticipate, prevent, and/or ameliorate future ethical problems. For example, a clinician may establish specific informed consent procedures to follow when prescribing off label or when prescribing agents with high addiction potential. Similarly, researchers can build safeguards into their protocols, such as clearly defined benchmarks for ongoing consent for participation in trials and appropriate disenrollment and referral procedures for participants who experience relapse during medication-free intervals (Roberts 1999). As a final example, the

potential harms associated with conflicts of interest may be anticipated and prevented by identifying and appropriately managing overlapping roles and conflicting interests.

TABLE 67–1. Essential ethics abilities in psychopharmacology

The ability to identify the ethical features in caring for patients or conducting research
The ability to anticipate ethically risky or problematic situations
The ability to see how the physician's own life experience, attitudes, and knowledge may influence the care of the patient
The ability to identify one's areas of expertise (i.e., scope of clinical or research competence) and to work within these boundaries
The ability to gather additional information and to seek consultation and additional expertise in order to clarify and, ideally, to resolve ethical conflicts
The ability to build additional ethical safeguards into one's work

TABLE 67–2. Glossary of ethics terms

Altruism. The virtue of acting for the good of another rather than for oneself, at times entailing self-sacrifice.
Autonomy. Literally "self-rule." In medical ethics, autonomy is the ability to make deliberated or reasoned decisions for oneself and to act on the basis of such decisions.
Beneficence. An action done to benefit others. The principle of beneficence in medicine signifies an obligation to benefit patients and to seek what will do them good.
Coercion. The use of some form of pressure to persuade or compel an individual to agree to a belief or action.
Compassion. Literally, "suffering with" another person, with kindness and an active regard for his or her welfare. Compassion is more closely related to empathy than to sympathy, as sympathy connotes the more distanced experience of "feeling sorry for" the individual.
Confidentiality. The obligation of physicians not to disclose information obtained from patients or observed about them without their permission. In clinical care, it entails taking precautions to protect the personal information about patients. Confidentiality is a privilege linked to the legal right of privacy and may at times be overridden by exceptions stipulated in law.
Conflict of interest. In medicine, a situation in which a physician has competing roles, relationships, or interests that could potentially interfere with the ability to care for patients. Such situations may naturally occur in clinical care and research, and they are not inherently unethical. They must be recognized and managed appropriately to safeguard the well-being of vulnerable individuals (e.g., patients, research participants) and to prevent exploitative practices.
Empathy. Entering into someone else's frame of reference in terms of thoughts, feelings, and experiences, to have an authentic understanding of the other person's experiences imaginatively as one's own.
Fidelity. The virtue of promise keeping, truthfulness, and honor. In clinical care, it refers to the faithfulness with which a clinician commits to the duty of helping patients and acting in a manner that is in keeping with the ideals of the profession.
Fiduciary. An entity in a position of trust with a duty to act on behalf of another, for the other's good. Physicians are fiduciaries with respect to their patients.
Honesty. A virtue in which one conveys the truth fully, without misrepresentation through deceit, bias, or omission.

Human dignity. The principle that every person, intrinsically, is valued and worthy of respect. In medical ethics, every patient is believed to have innate and inalienable worth as a human being that requires he or she be treated with respect and compassion and full interpersonal regard as expressed in attitudes, behaviors, and nondiscriminatory practices.

Informed consent. In the clinical setting, a legal and ethical obligation for clinicians to inform patients about their illness and alternatives for care and to assist them in making reasoned, authentic decisions about treatment. In the research setting, a similar obligation of a researcher to inform participants about the research protocol and help them make reasoned, authentic decisions about research participation.

Integrity. A virtue literally defined as wholeness or coherence. It connotes professional soundness and reliability of intention and action.

Justice. The ethical principle of fairness. Distributive justice refers to the fair and equitable distribution of resources and burden through society.

Medical decision making. The intentional process associated with making a choice in clinical care. It pertains to a patient's capacity to make decisions related to his or her health or health care and to the clinician's process of deliberation, consultation, and data gathering that results in the development of a diagnosis and of therapeutic alternatives for a patient.

Medical negligence. The legal concept of a breach of duty of medical care. It rests on the existence of a duty of care, failure to fulfill that duty, and resultant harm.

Nonmaleficence. The duty to avoid doing harm.

Personhood. Having full moral status as a human being.

Quality of life. The expression of a value judgment by an individual regarding the experience of life as a whole or some aspect of it.

Respect. The virtue of fully regarding and according intrinsic value to someone or something. In clinical care, it is reflected in treating another individual with genuine consideration and attentiveness to that person's life history, values, and goals.

Self-understanding. Awareness of one's own values and motivations. Self-understanding based on insight and careful self-scrutiny is a key ethics skill of special importance to mental health care ethics.

Therapeutic boundaries. The set of concepts, rules, and duties that structures the clinician–patient relationship to ensure psychological safety, to optimize therapeutic benefit, and to prevent potentially exploitative practices.

Trustworthiness. A virtue that pertains to a disposition that inspires confident belief in and reliance on the physician's character and ability to act beneficently and honestly.

Voluntariness. The attribute in which a belief or act derives from one's own free will and is not coerced or unduly influenced by others.

Vulnerability. The capacity to be wounded or hurt physically, emotionally, spiritually, or socially and being without the means to defend or advocate for oneself fully.

TABLE 67–3. Ethical tensions in clinical psychopharmacology

Clinical situation	Relevant ethical principles	Conflicts and tensions
A patient refuses a medically indicated medication.	Autonomy and beneficence	The patient's right to make his or her own decisions is in tension with the physician's duty to do good by providing medically

Clinical situation	Relevant ethical principles	Conflicts and tensions
		indicated treatment.
A colleague asks a psychiatrist to write a prescription for a sleep medicine.	Nonmaleficence	The desire to oblige a colleague may conflict with the psychiatrist's duty to avoid harming a patient by prescribing without conducting a thorough medical evaluation and establishing a treatment relationship.
A rural psychiatrist's patient needs a treatment that the psychiatrist is not competent to provide; no other practitioner is available.	Nonmaleficence	The psychiatrist's duty to avoid harming the patient by practicing outside his or her scope of competency is in conflict with the obligation to avoid harming the patient by leaving him or her without a treatment provider.
A pharmaceutical company offers a psychiatrist an unusually large fee for referring patients to a research trial.	Fidelity	Financial self-interest threatens the psychiatrist's duty to remain faithful to the goals of treatment and to the role of a healer.
A patient's severe psychiatric illness responds only to a medication that is contraindicated because of a concomitant medical condition.	Nonmaleficence and beneficence	The psychiatrist's duty to do good by treating the psychiatric illness is in tension with the risk of worsening the medical condition.
A pregnant woman has a severe mental illness that responds best to psychotropic medication that may pose a risk to her fetus; the patient is ambivalent about the pregnancy and her treatment options.	Nonmaleficence, beneficence, and respect for autonomy	The psychiatrist's duty to do good by treating the psychiatric illness is in tension with the possibility of harming the fetus. Respecting the patient's autonomous right to select a treatment is complicated by her ambivalence.

SELECTED ETHICAL ISSUES IN PSYCHOPHARMACOLOGY

The Doctor–Patient Relationship

The therapeutic relationship in medicine and psychiatry is rooted in the principles of beneficence and respect for autonomy. Historically, an emphasis on beneficence over autonomy has been the hallmark of paternalism, in which the physician acts benevolently and at times unilaterally, like a parent, in dealings with patients. By contrast, an emphasis on respect for autonomy over beneficence in the therapeutic relationship highlights the importance of patients' rights. Patients' rights in pharmacotherapy have been described as including the following: "access to treatment; provision of necessary information [about treatment]; the freedom to accept or refuse treatment; and a voice in the selection of specific drugs and the conditions under which to take them" (Brown and Pantelis 1999, p. 257). At its most extreme, a strictly beneficence-based practice may diminish the ill individual, violating the cardinal ethical principle that governs all actions in medicine and human science: respect for persons. On the other hand, a strictly autonomy-based practice at its most extreme appears to be akin to a mere business transaction—a trade of goods and services between two "equal" individuals, one with a product or service and the other with an identified interest or

need, with no specific moral obligation between the two parties (Dyer 1988; Wise 2007).

To avoid these two extremes, Dyer suggests that the therapeutic relationship be viewed as a fiduciary partnership (Dyer and Bloch 1987). A *fiduciary* in health care is one whose actions are worthy of trust. A *fiduciary partnership* has been described as being characterized by "sincerity without reserve" and "loving care" (Guttentag 1968). Through such a trusting partnership and through the process of informed consent, physicians and patients may achieve a relationship in which optimal healing can occur (Brown and Pantelis 1999; Dyer 1988; Roberts and Dyer 2004). The physician provides information and compassionate care while respecting the patient's privacy, values, and preferences in a manner that helps the patient identify and adhere to optimal treatments.

Although the psychodynamics of the doctor–patient relationship have been most exhaustively studied in the psychoanalytical literature, many features pertain across a wide range of clinician–patient encounters (Roberts and Dyer 2004). In all types of health care settings, patients have needs and clinicians have the knowledge and ability to attempt to meet those needs, establishing a power differential between clinician and patient. Transference and countertransference arise and can complicate treatment if not recognized and addressed (Gabbard 2000; Tasman et al. 2000). For example, patients may act out feelings of negative transference through treatment nonadherence, and a prescriber may act out countertransference anger toward such a patient by becoming overly authoritative (Gabbard 2000; Tasman et al. 2000). Furthermore, a therapeutic frame exists in the practice of psychopharmacology as in the practice of psychotherapy. This frame may differ in some ways—frequency of appointments is the most obvious—but like any therapeutic frame, it has boundaries that must be maintained by the clinician.

Maintenance of Therapeutic Boundaries in Psychopharmacological Treatment

Gabbard (1999) has defined professional boundaries as the "'edge' or limit of appropriate behavior by the psychiatrist in the clinical setting" (p. 142). Boundaries include the circumstances under which patients are seen—such as for a set fee, in the physician's office, during office hours—and the professional conduct of the psychiatrist during the encounter. Maintaining appropriate boundaries demonstrates respect for the individual patient, who is in an unequal relationship with the clinician and therefore vulnerable to possible exploitation.

Boundary violations occur when clinicians act in a way that transgresses the normal professional limits and may harm the patient. Sexual contact between psychiatrist and patient is a severe boundary violation that has been shown to cause lasting damage to patients (R. S. Epstein 1994b), is prohibited by the American Psychiatric Association (2001), and is illegal in many jurisdictions (Milne 2002). Characteristics of psychiatrists who commit sexual boundary violations include narcissistic pathology, poor training, and isolation from colleagues (R. S. Epstein 1994a). Insights drawn from therapeutic work with physicians and therapists who have had sexual contact with patients and from analysis of cases where ethics complaints have been brought forward related to sexual boundary violations indicate that these clinicians may not appreciate the exploitative nature of their actions. The "lovesick" caregiver, as Gabbard (1999) suggests, may in fact be "well-intended" but has confused his or her own need for fulfillment and gratification with the needs of the patient and has failed to adhere to the primary ethical imperatives of clinical care: respect for persons, beneficence, and nonmaleficence. Nonsexual boundary violations include engaging in other forms of physical contact, seeing patients outside the office or hospital setting, accepting large gifts from patients, or exploiting patients for social or business purposes (R. S. Epstein 1994a; Frick 1994; Gabbard 1999). The defining characteristic of these violations is the subordination or eclipse of the patient's needs by the self-interested objectives, whether intentional or not, of the professional.

As opposed to boundary violations, boundary *crossings* are subtle transgressions that serve to advance the treatment—for example, accepting a token gift to help a patient feel more comfortable in

the therapeutic relationship (Gabbard 1999; Gutheil and Gabbard 1993, 1998). Boundary crossings are therefore not inherently unethical. Still, they should be undertaken in a deliberate fashion (e.g., after being discussed with a peer, supervisor, or consultant; occurring only in certain contexts or with certain kinds of issues or with healthier patients) and always be oriented toward the goals of treatment.

Most psychiatrists have been trained in the importance of respect for boundaries in the therapeutic relationship in psychotherapy; in psychopharmacological practice, such respect is no less crucial, although the less intense nature of the therapeutic relationship may make it more difficult for clinicians to notice a tendency toward making subtle boundary violations. Seeking supervision or consultation can help ensure that what the clinician perceives is a useful boundary crossing is not potentially detrimental to the patient—for example, making a house call to visit a favorite patient when that is not one's usual practice.

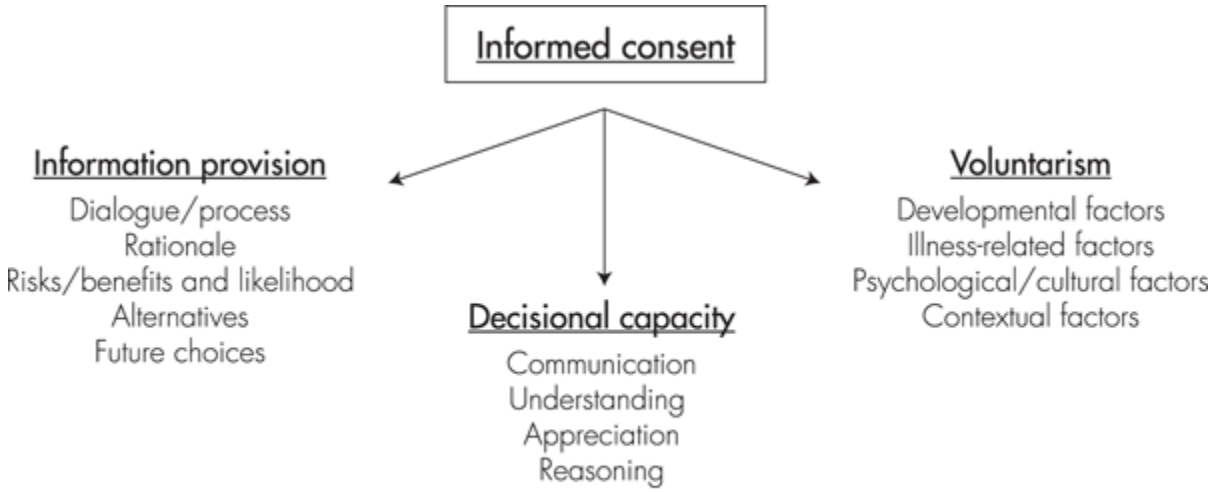
Informed Consent for Psychopharmacotherapy

In clinical care, the process of informed consent is a fundamental and ethically important activity of the physician. Informed consent represents an ongoing exchange between physician and patient in which the clinician fulfills the role of teacher as well as diagnostician and healer. Through this process, physicians demonstrate respect for patients, enhance patients' ability to act in concert with their authentic wishes, and strengthen the therapeutic alliance. Informed consent is an example of shared decision making (R. M. Epstein et al. 2004), as opposed to the paternalistic view of medical decision making as solely the domain of the physician (Faden and Beauchamp 1980). Shared decision making appears to increase treatment adherence and improve doctor–patient communication (R. M. Epstein et al. 2004).

Informed consent is a legal as well as an ethical concept. The 1914 landmark opinion of the New York Court of Appeals in *Schloendorff v. Society of New York Hospital,* written by Justice Benjamin Cardozo, set forth the basic principle of American law regarding consent to medical procedures: "Every human being of adult years and sound mind has a right to determine what shall be done with his own body; and a surgeon who performs an operation without the patient's consent commits an assault, for which he is liable in damages." Subsequent court cases have enshrined in law the ethical principle that a patient's consent must be truly informed (Morris et al. 2005).

Informed consent has been described as consisting of three elements, each of which is vital to the process: information provision, decision-making capacity, and voluntariness (Figure 67–1) (Faden et al. 1986; Roberts and Dyer 2004). These elements are described below:

1. Information provision is the domain of the provider, who must give patients all relevant information about the potential advantages and disadvantages of contemplated treatment, as well as any viable alternatives to the treatment, including no treatment at all. Information provision is a process that requires dialogue between the patient and the provider. From a legal standpoint, the amount and type of information that must be disclosed vary across jurisdictions. Some adhere to a *professional standard*—that is, the amount and type of information that most physicians would disclose to patients. Other states use the *reasonable person standard*—that is, the amount of information a reasonable person would want to know. It is not possible to create a one-size-fits-all information-sharing session that can be used for any patient with a given diagnosis. The clinician should be attuned to the intellectual, emotional, and relational needs of the patient in deciding how to provide information about treatment options.
2. The second feature of informed consent is the decision-making capacity of the patient, which is itself defined as consisting of four abilities (Appelbaum and Grisso 1995). First, the patient must be capable of communicating a preference. This is demonstrated by patients who have the physical ability to speak, write, or gesture in such a way that others can understand. Second is the ability to comprehend the information necessary for making the medical decision, a primarily cognitive task that is affected by factors such as



patients' educational background. Because patients vary in the ability to comprehend complex medical data, providers should use language, examples, and illustrations tailored to the needs of individual patients. Third is the ability to appreciate the significance of the medical decision that is to be made. Although a patient may comprehend the facts about the medical situation (e.g., "I understand that lithium is an effective treatment for mania"), lack of insight may impair the ability to appreciate how that information is relevant to the current situation (e.g., "I am not manic and therefore have no need to take lithium"). The ability to appreciate the significance of medical information is influenced by one's beliefs and values, and it can be difficult to thoroughly assess whether someone is truly capable of appreciating clinical material (Roberts et al. 2008a). The final element of decisional capacity is the ability to reason—to weigh options and consequences in order to come to a considered judgment. The outcome of this reasoning process does not necessarily have to be considered a rational decision by others.

Predictable variations in decisional capacity occur with various illness states. Patients with delirium are likely to have waxing and waning capacity. Patients with dementias generally become less capable of making treatment decisions as their disease progresses. Individuals with psychotic disorders may be decisional at some times in the course of their disorder and nondecisional at other times. Those who are depressed may become more pessimistic about the possibility of successful treatment if the depression worsens. Clinicians who are aware of these likely variations in cognitive capacity may properly take advantage of moments when patients are decisionally capable to clarify patient preferences regarding their treatment and persons who may act as alternative decision makers for them.

3. The third element of informed consent is the patient's level of voluntariness, or *voluntarism:* the ability to make choices that are free from coercive pressure and are in concert with the individual's authentic wishes. Voluntarism has been described as depending on four types of factors: 1) developmental factors; 2) illness-related factors; 3) psychological and cultural factors; and 4) contextual factors and pressures (Roberts 2002c).

   As an example, a 19-year-old male patient with new-onset psychosis may have numerous factors bearing on his ability to voluntarily consent to the use of antipsychotic medication. These could include the patient's developmental level and amount of relevant life experience; the nature of the psychotic process; whether he has received involuntary treatment in the past (e.g., medication, hospitalization); his personal and cultural beliefs about suffering, mental illness, and the use of medications that affect the brain; and pressures from family, the treating physician, and perhaps the courts. Clinicians who are aware of the presence of these issues can anticipate and address them when informing the patient about treatment options. Understanding the array of influences on voluntarism, moreover, can help clinicians to target ways to enhance the voluntary nature of their patients' decision-making process—for example, by providing emotional support for someone who has symptoms or experiences that have felt disempowering in the past, by allowing the patient ample time for making decisions that are not urgent, and by providing an opportunity to share information with valued family members who might help advocate for the patient's preferences—or, alternatively, by helping to shield the patient from inappropriate pressure by someone who does not have the patient's wishes and best interests at heart.

When are decisional capacity, voluntarism, and information sharing considered sufficient to enable a patient to consent to or refuse medication treatment? There is no single answer to this question, and many experts adhere to the notion of a *sliding scale for consent* (Drane 1984), in which the standards for consent are dependent on the likely seriousness of risks accompanying the decision. Standards for consent for a low-risk treatment, such as the one-time use of diphenhydramine for insomnia, are generally considered lower than standards for consent to a treatment with a greater potential for adverse effects, such as clozapine or a monoamine oxidase inhibitor. Of course, individuals who are clearly incapable of comprehending the information necessary to make a decision regarding their medical care, of appreciating the implications of their consent to or refusal of contemplated care, of reasoning rationally in arriving at a treatment choice, or of communicating their decision are not able to negotiate the process of giving or withholding informed consent for even low-risk pharmacotherapy.

The sliding scale paradigm suggests that, in general, there is a higher standard for refusing recommended treatment than for consenting to it, because treatment refusal typically involves higher risk. This is an important concept, ethically and clinically. The naïve individual may initially reject the notion that, under some circumstances, there appear to be different standards for accepting or refusing treatments. In fact, the standards are not different—it is just that the standard for decision making is determined by the level of risk and benefit hinging upon the decision. In other words, use of a very dangerous medication for a mild illness will entail an extremely high standard for decision making, as it should. Alternatively, the decision to decline a relatively benign medication for a severe and life-threatening illness will also entail an extremely high standard for decision making. This approach to assessing an individual's capacity for clinical decision making is governed by the principle of beneficence—seeking to do good—and, even more, by the principle of nonmaleficence—seeking to avoid harm.

Exceptions to Informed Consent and Involuntary Intervention

There are a few exceptions to the ethical and legal requirement to obtain the informed consent of patients before providing treatment. Necessary medical treatment may be given in emergencies to those who are unconscious or otherwise unable to give informed consent. Treatment may also be provided to individuals who lack decisional capacity if consent is obtained from the appropriate

alternative decision maker, such as the parent of a child or the health care proxy of a decisionally incapable adult. This is discussed in more detail below. Traditionally, it was also acceptable to provide treatment without consent to patients who were considered likely to become too emotionally distraught from the disclosure of relevant medical information to be able to rationally choose to accept or refuse proposed treatment (Morris et al. 2005). This practice, known as the *therapeutic privilege,* has fallen substantially out of favor with ethicists, courts, and physicians in recent years as paternalistic approaches to patient care have given way to the contemporary ideal of shared or participatory decision making.

The pharmacotherapy of children requires special attention to the issues of informed consent. Parents and legal guardians of children and unemancipated minors have the legal right to make decisions about medical treatment for minor patients. The age of majority differs in some jurisdictions for obtaining mental health, substance abuse, or reproductive health treatment, so clinicians who treat children and adolescents should be familiar with local laws regarding the age of majority. Even if a guardian must provide consent, minor children should also be educated about the medications they are being prescribed, in a manner that is appropriate to their cognitive level. According to the "rule of sevens" guideline (Hoop et al. 2008), cognitively normal children younger than about 7 years are presumed not to have the capacity to give informed consent; those between about ages 7 and 14 years are capable of some level of decision making; and adolescents 14 years and older have many of the abilities required to make an informed treatment decision.

In the case of pharmacotherapy for patients who are decisionally compromised due to cognitive impairment, the judicial appointment of a legal guardian to make health care decisions is often required. During the informed consent process, the guardian must take into consideration any previously expressed wishes of the patient regarding treatments. For example, a spouse who is the guardian of a patient with dementia should endeavor to make medical decisions that align with the previously expressed wishes of the ill spouse—a standard known as *substituted judgment.* When a guardian has no idea of a patient's wishes, as is the case with patients with severe developmental disorders who have never been able to formulate or express treatment preferences, the guardian may make treatment decisions based on what is believed to be in the best interest of the patient.

In some jurisdictions, patients with mental disorders whose ability to make decisions fluctuates during the course of illness may create an advanced directive for psychiatric care, to give health care providers guidance regarding treatment preferences should the patient become incapacitated at a later time. In the absence of such a document, legal interventions allow for treatment permission to be granted by a substitute decision maker (sometimes a judge or a medical professional not involved in the care of the patient). The decision maker may rely on substituted judgment if the wishes of the patient (expressed while the patient was decisional) are known, but often the decision maker must make a determination of what he or she believes to be in the best interest of the patient.

Involuntary treatment may be necessary for patients whose mental illness makes them a danger to themselves or others, and it has been ethically justified on the grounds of beneficence—to do good both for the patient and for any person who may be endangered by the patient's actions. Involuntary treatment represents a rare occurrence in contemporary medicine, in which the clinician's duty of beneficence is allowed to trump the duty to respect patient autonomy. The ethics of involuntary treatment has long been a matter of discussion (Bartlett 2003; Levenson 1986–1987; Rosenman 1998), with a few experts and advocates arguing that any such treatment should be impermissible as a violation of human rights (Szasz 1976) and a larger contingent seeing it as necessary and beneficial, if implemented with appropriate checks and balances. Especially in the extreme situations that lead to involuntary treatment, clinicians should endeavor to respond to patients therapeutically, compassionately, and respectfully (Roberts and Dyer 2004). Strategies for doing so are presented in Table 67–4.

TABLE 67–4. Working therapeutically with patients receiving involuntary medication treatment
Understand treatment refusal as a possible expression of distress
Ascertain the reasons for refusal
Allow the patient to discuss his or her preferences and fears
Explain the reason for the intervention in simple language
Offer options for the disposition of treatment
Appropriately enlist the assistance of family and friends
Request support from nursing and support staff
Assess the patient's decisional capacity and, if necessary, have recourse to the courts
Attend to side effects—both long- and short-term, serious and bothersome
Work to preserve the therapeutic alliance
Consult with the patient's legal guardian, or utilize his or her advance directive where appropriate

Working With "Difficult" Patients

A wide range of clinical issues leads physicians to perceive patients as "difficult": they may have severe or treatment-resistant illness, or they may have a personality disorder or be self-destructive, needy, angry, help rejecting, nonadherent, narcissistic, rich, famous, or simply too much like the clinician in some crucial way (McCarty and Roberts 1996; Robbins et al. 1988). Treating such patients can be deeply challenging, because their maladaptive behaviors may push clinicians toward reactions that lack compassion or are even unethical (Gabbard 2000; Roberts et al. 2008b).

Consider, for example, the reactions of the prescribing physician treating a patient whose major depressive disorder has continued unabated for several months despite adequate trials of several antidepressant medications. The clinician's frustration at the situation may cause him or her to emotionally detach from the treatment relationship, blame the patient for the treatment failure, or become overzealous and suggest unnecessarily risky treatments. Another example is the clinician whose patient with schizophrenia does well while taking an antipsychotic medication but because of lack of insight is unable to adhere to the medication for any extended period. Repeated cycles of clinical improvement, stabilization, nonadherence, and then decompensation may exhaust the clinician's ability to work compassionately with the patient. A third example is the patient who is perceived as medication seeking. Clinicians feel varying levels of comfort with and tolerance for working with patients who seek care because of a desire for benzodiazepines, psychostimulants, or cosmetic pharmacology via selective serotonin reuptake inhibitors as personality enhancers.

A three-step approach to working therapeutically with difficult patients has been described (McCarty and Roberts 1996). As a first step, the clinician analyzes the situation to understand precisely what makes it difficult. Next, the clinician adjusts his or her perspective to view the problematic behavior as a *clinical sign,* an observable indication or form of communication that is key to better understanding the patient and the treatment relationship. Finally, the clinician pauses and reflects before reacting to the patient's behavior. Consultation or supervision may also be invaluable in helping the clinician develop a therapeutic and respectful response.

This framework suggests that a useful response to the medication-seeking patient is to compassionately and nonjudgmentally explore with the patient the reasons for the request for the

medication—rather than responding reflexively with an adversarial, withholding stance. This approach may allow the patient to discuss feelings and/or symptoms that had not previously been fully disclosed. This strategy should also strengthen the therapeutic alliance and help ensure that the patient remains in treatment even if the request for medication cannot be fulfilled. When talking with a medication-seeking patient about such a request, it is useful to maintain one's focus on the actual risks and benefits of the requested treatment for the patient, including a forthright discussion of the risks of addiction or abuse. It is also important to give genuine and careful consideration to the merits of the request, which may in fact be justified by the patient's symptoms. In rare cases, the psychiatrist may have evidence that the request for unnecessary prescriptions truly represents antisocial acting out by the patient. The clinician is of course obligated to demur in such situations.

A similar strategy can be employed when working with chronically nonadherent patients. The treating psychiatrist should work compassionately with the patient to learn why the patient has not adhered to the treatment plan. One possibility is lack of decisional capacity; another is an inadequate understanding of the benefits of taking the prescribed medication on a regular basis. Other issues that may underlie nonadherence include lack of insight into the illness, forgetting doses or forgetting to refill prescriptions, inability to pay for the medication, homelessness or other chaotic living situations that make routine medication use difficult or impossible, bothersome side effects such as weight gain and sedation, or personal/cultural/religious beliefs about mental illness and medications (Cooper et al. 2007). Once the underlying reasons for nonadherence are identified, the psychiatrist can work with the patient to develop a therapeutic strategy that is more congruent with the patient's needs and preferences. This may involve providing psychoeducation, prescribing a less costly medication, enrolling the patient in a financial assistance program, changing medications or doses to ameliorate side effects, prescribing injectable depot preparations, or enrolling the patient in case management services.

Ethical Use of High-Risk Pharmacotherapy

Prescribing psychopharmacological treatments with a high potential for adverse consequences requires keen attention to ethical issues and to the informed consent process. For example, consider the case of a formerly suicidal patient whose severe bipolar disorder responds only to divalproex sodium but who has just been diagnosed with a low-grade chronic infection with hepatitis C. Further treatment with divalproex carries with it an increased risk for severe liver damage in such a patient, while discontinuing the medication carries the risk of relapse and perhaps suicide. The clinician is faced with the possibility of causing serious harm with either action.

To handle this type of situation in a clinically and ethically appropriate manner, the clinician would be wise to do the following:

- Consider all clinical options.
- Look for ways to safeguard the patient (for example, through ordering laboratory tests more frequently, involving the family, or hospitalizing the patient).
- Consult with more experienced colleagues or obtain a second opinion.
- Engage the patient in a thorough discussion of the options and their risks.

Most likely, there will be a range of ethically appropriate responses, and patient preferences should guide the decision. If the patient is unable or unwilling to participate in the decision, it may be possible to bring family members or other loved ones into the process. Such situations are likely to provoke anxiety or other strong emotional responses among clinicians; self-awareness may prevent clinicians from allowing those responses to subtly or overtly influence the patient's decision.

Ethical Use of Long-Acting Medications

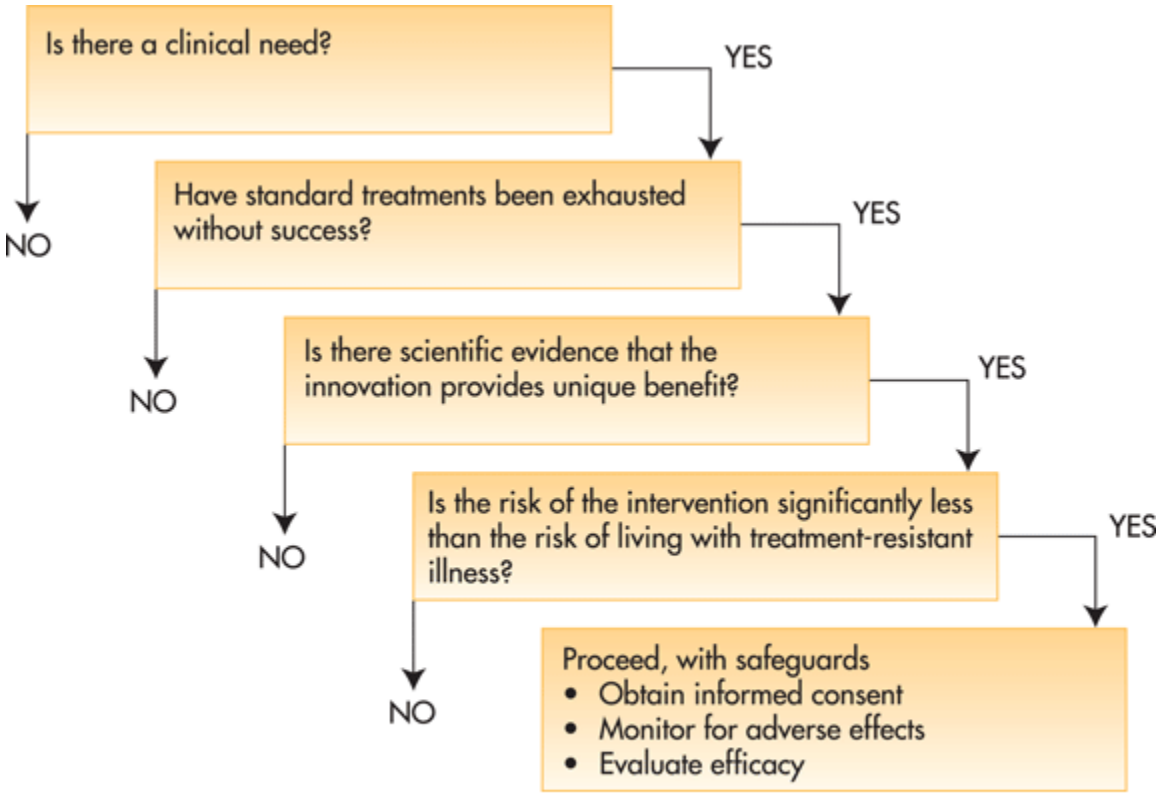
Injectable depot antipsychotic medications (long-acting preparations) are an important treatment

option for many patients, particularly those who have the most severe and persistent psychotic disorders and those for whom medication adherence presents a major challenge. The scientific literature suggests that these agents may offer some benefits over oral preparations, in terms of pharmacokinetics and bioavailability, convenience, cost, treatment adherence, and outcomes such as hospitalization (Barnes and Curson 1994; Gerlach 1995; Kane et al. 2003; Knapp et al. 2002; Marder et al. 2002; Swartz et al. 2001). The risks appear similar to those of oral preparations of the same agent, but there may be additional difficulty in managing side effects or adverse events should they occur (Adams et al. 2001; Glazer and Kane 1992).

From an ethical perspective, the use of depot medications has traditionally raised concerns about coercion and impaired voluntarism (Patel et al. 2005; Roberts and Geppert 2004). As mentioned above, voluntarism is the ability to make authentic decisions freely about one's life and body. For example, a patient who decides to discontinue an oral antipsychotic can rid his or her body of the drug within a relatively short period of time simply by not taking the next dose. A patient who is prescribed a depot preparation of the same medication does not have this level of control. If the patient wishes to discontinue the drug, the ability to act on this desire may be thwarted by the medication's extended half-life, and the patient may be forced to live with the drug's effects for days to weeks (Wiles et al. 1990). In effect, the drug's pharmacokinetics coerces the patient to remain on the medication for an extended period. The flip side of this is that the drug's pharmacokinetics may save patients from the suffering that could occur if doses are accidentally missed or a prescription refill is forgotten. Moreover, the patient may have improved decision-making abilities for longer periods of time and therefore have paradoxically greater ability to give informed consent (or refusal) for treatment while on depot treatments (Roberts and Geppert 2004). Nevertheless, the persistence of these drugs in the body raises deep concerns about their use in decisionally incapable patients, because the long-acting medication may persist in the patient's body long after the patient's decision-making capacity is restored (Eastwood and Pugh 1997; Roberts and Geppert 2004).

Concerns about coercion and impaired voluntarism must be balanced by psychiatrists' ethical duty of beneficence, which may be exemplified by prescribing depot preparations when they have demonstrated advantages over oral agents. The number of clinical situations in which these preparations are indicated may grow now that a long-acting form of an atypical antipsychotic has been introduced (Möller 2007). Bolstering this view are empirical data regarding patients' feelings about being prescribed depot preparations. Although these data are limited, a 2001 review of the literature found that most patients expressed positive attitudes toward depot forms of typical antipsychotics (Walburn et al. 2001). Much more empirical work in this area is needed to further clarify patients' attitudes, including opinions about depot preparations of atypical antipsychotics. Meanwhile, prescribing long-acting medications can be ethically justified on beneficent grounds, especially for decisionally capable patients with severe and persistent illness who have difficulty adhering to treatment (Roberts and Geppert 2004). In fact, the underuse of depot preparations among populations of patients who could benefit from them may be perceived as an ethical failing of the health care system to provide fair and equitable access to innovative forms of treatment (Heres et al. 2006; Roberts and Geppert 2004).

Ethics of Off-Label Prescribing and Clinical Innovation



Every day, many patients seek psychiatric care for severe symptoms for which there are few or no treatments approved by the U.S. Food and Drug Administration (FDA). The psychiatric treatment of special populations, especially children and adolescents, is profoundly hindered by the scarcity of clinical evidence regarding the efficacy and safety of psychotropics in these patients. In response, many psychiatrists prescribe medications *off label*—that is, for conditions or populations for which the FDA has not, or not yet, given approval. This practice has at times been characterized in the popular media and on the Internet as an unprofessional deviation from medical norms (Harris 2007), although

it is common practice for nonpsychiatric drugs such as chemotherapeutic agents, and some indications (such as lithium for suicide prevention) are believed to lack FDA approval primarily because no pharmaceutical company has sought the indication (Daly 2007).

Off-label prescribing falls under the rubric of *clinical innovation* if its intention is to help individual patients, and it is considered *medical research* if it is done in a systematic attempt to gather generalizable data (U.S. Department of Health and Human Services 2001). Clinical innovation can be considered ethically justified if it occurs under specific circumstances, as shown in Figure 67–2 and described below:

1. There must be a substantial clinical need. For example, off-label prescribing is not justified if a patient presents with a previously untreated condition for which a safe, effective, and FDA-approved medication exists.
2. Standard treatment efforts must have been exhausted without success. All medications that have been approved for the condition and would be appropriate for the individual must have been given reasonable trials.
3. Scientific evidence must exist in support of the innovation providing a benefit. The amount of evidence required depends on the severity of the condition, the known risks and benefits of the treatment, and the patient's preferences. For example, relatively modest evidence of efficacy may be required to justify the use of an innovative agent that has excellent safety data if the patient prefers to try the new treatment and has severe treatment-resistant symptoms.
4. The anticipated likely risks of the intervention *and* the relatively rare but entirely possible risks must not be significantly greater than the risks associated with the underlying illness or condition. For example, the use of clozapine as an innovative treatment for transient mild anxiety would be inappropriate given the risks of significant side effects associated with this drug. In addition, appropriate safeguards to identify risks and side effects must be feasible and put in place.

FIGURE 67–2. Decision tree for ethical use of clinical innovation.

When off-label prescribing or another clinical innovation is indicated by the reasons listed above, treatment may proceed with appropriate safeguards. The foremost safeguard is the process of obtaining informed consent, as described above (see "Informed Consent for Psychopharmacotherapy"). Information provision is an important part of this process, and the psychiatrist should make clear to the patient that the FDA has not approved this use of the medication. The psychiatrist should clarify the status of the science supporting the off-label use of the medication and should describe how widespread the off-label use is in psychiatric practice. Only by clearly informing the patient of the status of the medication can the psychiatrist ensure that the patient has the opportunity to give genuinely informed consent to the treatment. When treating decisionally incapable patients, clinicians should provide all information to the appropriate alternative or substitute decision makers. Other safeguards include clinical monitoring for adverse effects, evaluating the medication's efficacy, and reevaluating both the patient's need for the medication and the scientific evidence supporting its use on an ongoing basis.

MANAGEMENT OF THE SPLIT-TREATMENT RELATIONSHIP

The relationship of a prescribing psychiatrist to affiliated psychologists or other therapists who care for the same patients can present numerous issues that affect patients' care, including interpersonal conflicts, confidentiality concerns, splitting, and scope-of-practice issues (Lazarus 2001). Asking patients to provide a continuing *release of information* agreement that allows the prescriber and other therapists to talk about the case over time is an important step in ensuring that communication is adequate to keep the goals of psychotherapy and psychopharmacology aligned. It is also important that psychiatrists and therapists who treat patients with pharmacotherapy and psychotherapy in a split-therapy model do so in a manner that respects and supports the contribution of the other professional. Different mental health disciplines have different theoretical orientations and practices, which can lead to disagreements among professionals regarding the appropriate care of the patient. Frequent, open, and respectful communication is necessary to ensure that patient care is optimal

(Roberts et al. 2008b).

ETHICAL ISSUES IN PSYCHOPHARMACOLOGICAL RESEARCH

To be ethical, clinical research must meet several criteria, as summarized below (Emanuel et al. 2000; Roberts 1999, 2001a):

- The research question must be important.
- The study design and methodology must be adequate to answer the question and must minimize risks and maximize benefits.
- By training and experience, research personnel must be capable of performing the research in a scientific and ethical manner.
- Participants must be selected and recruited fairly and then be adequately informed about the study.
- Study data must be kept confidential.
- The entire process must be overseen by peer reviewers such as members of institutional review boards.
- Results must be reported in an appropriate manner.

All of these ethical considerations pertain to medication trials in psychiatry; perhaps the most controversy has surrounded issues related to informed consent (Roberts 2002b; Rosenstein and Miller 2003) and specific study design features such as the use of placebo control subjects and medication-free intervals (Carpenter et al. 1997; Roberts et al. 2003; Weijer and Appelbaum 1996).

Because psychiatric disorders may interfere with or disrupt a person's ability to receive and understand information, decision making, and sense of voluntarism, ethical concerns have long been raised about informed consent for psychopharmacological trials, especially for drugs to treat disorders associated with cognitive impairment or psychosis. However, efforts to protect psychiatric patients from exploitation in the research setting may, if applied too broadly, cause unintended harm and injustice by unfairly preventing entire diagnostic categories from receiving needed research attention (Roberts et al. 2008a; Rosenstein and Miller 2003). Empirical data on this issue have helped to establish that a broad-based approach may not be necessary or just. For example, survey data gathered by one of us (L.W.R.) suggest that schizophrenia patients are capable of making nuanced judgments about research participation (Roberts et al. 2000, 2003). Ethically rigorous methods for including decisionally impaired individuals in research include educational interventions to enhance their decision-making capacity (Carpenter et al. 2000; Dunn and Roberts 2005; Dunn et al. 2006; Moser et al. 2006), the use of alternative decision makers (Roberts et al. 2000), and the use of advance directives for research participation (Muthappan et al. 2005; Roberts and Dyer 2004).

Specific design elements in psychopharmacological research studies have also sparked controversy and debate (Carpenter et al. 1997, 2003; Charney et al. 2002; Frank et al. 2003; Kong and Whitaker 1998; Miller 2000; National Bioethics Advisory Commission 1998; Roberts 2002a; Roberts et al. 2001b; Rosenstein and Miller 2003). Among the most controversial procedures are the use of placebo control subjects and the use of medication-free intervals. In both cases, the investigator's ethical duty to provide meaningful data on research questions of high import is in tension with the duty to minimize risks to participants. Strategies for resolving this dilemma involve using the least risky protocol necessary to answer the research question and implementing safeguards to protect individual research participants (Emanuel et al. 2000; Roberts 1999; Roberts and Heinrich 2005). Appropriate safeguards might include close monitoring for symptom emergence, coupled with procedures to disenroll individuals for whom the risks of continued study participation become too great (Roberts and Heinrich 2005). An additional level of safeguarding is provided by having a data safety and monitoring board oversee the study (Carandang et al. 2007; National Institutes of Health 1998; Roberts 1999). Data safety and monitoring boards are independent groups of experts who are charged with monitoring study data and adverse events and are invested with the authority to halt or suspend studies if necessary to protect participants.

MANAGEMENT OF OVERLAPPING ROLES AND CONFLICTS OF INTEREST IN PSYCHOPHARMACOLOGY

Psychiatrists are called upon to fulfill multiple roles in contemporary society because of their combined expertise in mental illness, psychology, and medicine. Psychiatrists are intellectual resources not just for patients but also for students and trainees, agencies and institutions, and private industry. The result is that many psychiatrists, especially in academia, have ethical obligations related to multiple professional roles. The ethical demands of these overlapping roles may not fully align, however, and when this occurs, the physician may be placed in an ethical bind. For example, a physician-educator may feel caught between the pragmatic need to allow students to learn by practicing and the doctor's ethical duty to provide the best possible care to each patient. Similarly, the researcher with professional ties to both academia and industry may be caught between the obligation for truth telling inherent in the academic role and the requirement to protect trade secrets.

Managing such conflicts is an important task, the rules of which are still being written. The recent attention focused by media worldwide on the interaction of the pharmaceutical industry with physicians, and with psychiatrists in particular, makes this issue one of the most urgent unresolved ethical issues in our field (Harris 2007; Lewis et al. 2006). Conflicts of interest have traditionally been managed primarily through disclosure—that is, overlapping relationships are described explicitly so that others can make informed decisions about whether a role has been compromised. For example, many psychiatric journals have dealt with concerns about bias toward pharmaceuticals in research by creating policies requiring authors to disclose any relationships with pharmaceutical companies (Fava 2004; Perlis et al. 2005).

In the clinical sphere, there are no uniform standards for disclosing to patients that the clinician has a relationship with a pharmaceutical company, be it as a highly paid consultant, an occasional speaker, or a one-time attendee at a sponsored conference or dinner. One approach is to consider what information a patient might reasonably want to know about the psychiatrist's relationship with the pharmaceutical industry; if a patient could reasonably think that knowing about the details of that relationship would help him or her to understand why the psychiatrist is recommending a particular medication, the psychiatrist should make the disclosure. Following this logic, physician-scientists whose work is funded by the pharmaceutical industry should disclose this fact to their patients, particularly when recommending medications manufactured by that company.

Recently, methods of handling conflicts of interest that go beyond mere disclosure have begun to gain support (Fava 2007; Roberts and Dyer 2004; Roberts et al. 2008a, 2008b; Warner and Roberts 2004), such as the following:

1. Role separation: One strategy is deliberate role separation so that specific conflicts do not arise. This may require individuals to withdraw from certain activities. For example, clinician-researchers may design study protocols in which research participants receive clinical care from nonresearch personnel rather than from investigators affiliated with the study.
2. Role restrictions: Similarly, certain public institutions, such as state medical colleges, may not allow employed physicians to engage in roles that entail paid involvement with industry.
3. Oversight: A third strategy is institutional oversight and management. Policies in some academic departments, for example, may place limits on the amount of money that a faculty member can earn through involvement with industry.

The increased attention given in recent years to the problems associated with physicians' conflicts of interest is likely to continue. Professional societies in particular will need to continue to strive to minimize the damage such problems can cause both to clinicians' relationships with their patients and to the reputation of the field of psychiatry. Psychiatrists should closely follow developments in this area, keeping in mind the obligation of the medical profession and its organizations to deal with the

conflicts responsibly.

CONCLUSION

Psychopharmacology can be viewed as an intrinsically ethical activity, because it is designed to meet the moral imperative to relieve human suffering—and the suffering caused by mental disorders is indisputably widespread and devastating to individuals, families, and society. The clinical psychopharmacologist embodies the ethical principles of beneficence, nonmaleficence, and respect for persons whenever he or she thoroughly and empathically evaluates an individual with mental illness, carefully considers therapeutic alternatives, and engages the patient in a partnership for selecting and implementing a treatment.

As psychopharmacology has become increasingly relevant to psychiatric practice, it has also become important to identify and work through the unique ethical concerns that arise from this form of psychiatric treatment. One of our greatest needs is to establish procedures and safeguards appropriate to the current limited evidence base for psychopharmacological treatment. More research is needed, for example, to learn how well individuals with a variety of mental illnesses understand informed consent for treatment, particularly when it involves off-label prescribing, and how clinicians can best inform and safeguard patients when prescribing agents about which we have limited safety and efficacy data. Such research should provide evidence that helps us work ethically during this time of expanding growth in our understanding of the etiology and treatment of mental illness.
